US COLLEGE TEXTBOOK SUPPLEMENT

CUK - H06892 - 280 - RP410

When in London do as the Romans did— settle on the Barbican. (It's the perfect place for a conference.)

It's a long time since the Romans left. (About 1,500 years, in fact.) But you can still see traces of their occupation—including remains of the original Roman city wall.

The Barbican Centre is located in the heart of the City of London. So it's surrounded by centuries of history and culture plus the bustle and excitement of one of the world's leading financial communities.

The Barbican Centre itself, however, will be among the most modern and well equipped conference centres available.

There's a spacious conference hall. A variety of lecture theatres, seminar and committee rooms. A Film Theatre—with the most advanced audio-visual equipment. The Barbican Theatre. Interpretation facilities for six languages. A display and exhibition area. Plus a plentiful supply of bars and restaurants.

The Barbican caters for cultural appetites, too. The Royal Shakespeare Company will have its permanent home there. So will the London Symphony Orchestra. And the Guildhall School of Music and Drama. There's an Art Gallery. A Sculpture Court.

In other words, it's as civilised a forum for a conference as even the Romans could have dreamed of.

We're already taking bookings from 1981 onwards.

So, if there's anything more you'd like to know about the Barbican, just contact our Conference Sales Director.

And don't worry. She speaks English. Not Latin.

Barbican Centre 11 Cromwell Tower,
Barbican, London EC2Y 8DD, England. Telephone: 01-638 4141.

A display and exhibition area with a total of 64,000 square feet (5,500 square metres).

The Barbican Conference Hall comfortably seats 2,000 delegates.

A variety of lecture theatres, seminar and committee rooms to take anything from 5 to 265 people.

The Film Theatre seats 275 people.

The Barbican Theatre seats 1,150.

6 March 1980

No easy route to non-proliferation

NOWHERE has the interrelationship between politics and technology become more entangled than in discussing the relationship between the spread of nuclear energy and the proliferation of nuclear weapons. To candidates in the 1976 US presidential campaign, the issue seemed relatively straightforward: the greater the availability of plutonium — either through the reprocessing of spent nuclear fuel or through the deployment of fast breeder reactors — the greater the chance that some of this would be diverted to military purposes. Domestically, this philosophy became relatively easy to institutionalise in the Nonproliferation Act of 1977. Internationally it has fallen on sceptical ears.

The final report of the International Nuclear Fuel Cycle Evaluation (INFCE), initiated by President Carter over two years ago in an attempt to generate an international consensus behind the US strategy, has ended up a long way from endorsing his position. Admittedly there are parts of the final report from which the US can take satisfaction. For example, the nations taking part in the study agreed in general that sensitive nuclear facilities capable of producing weapons-grade material, such as reprocessing and enrichment plants, should be limited to as few countries as possible. And the report also confirms the US view that reprocessing is not a prerequisite for the disposal of nuclear wastes, and of marginal economic significance for thermal reactors.

US negotiators are also claiming solace from the fact that, although they have been unable to secure agreement on slowing down the deployment of fast breeders in the interests of non-proliferation, they have at least placed the issue more prominently than before on the international agenda. But this victory is, in many ways, a Pyrrhic one. INFCE did not agree to support any generalisations about the comparative proliferation risks of different fuel cycles. Indeed during its deliberations, the international deployment of fast breeder programmes, particularly in countries such as France concerned about guaranteed future access to uranium supplies, seems to have increased.

What the debate has lacked is a climate of trust. And this is as true for the relationship between the US and its fellow nuclear suppliers as between the suppliers and their customers. Many countries were upset, not so much by the US strategy, but by the apparent strong arm tactics by which it was seeking to impose it unilaterally. President Carter declared his intention that the US "Should provide strong leadership, using our own exports of nuclear fuel and technology to persuade other countries not to seek or sell the technology to make bombs." Many took exception to this attempt to use economic hegemony to force the rules of the game covering international trade in nuclear technology — particularly at a time when the US and European industries

seemed about to compete for lucrative third world markets.

The value of INFCE is that it has placed many of the issues raised by President Carter in broader perspective. We now know, for example, that there is unlikely to be any one technical fix to the proliferation question, and that the thorium-cycle does not necessarily offer any great advantages in this respect. We also know that the lack or adequacy of uranium supplies cannot be demonstrated simply. But whether we are any closer to reducing the dangers of proliferation is unclear.

One problem is that, whatever the detailed conclusions and recommendations of the report, any message that fast breeders are safe could, unless carefully handled, lead to unwarranted complacency. The report has successfully argued that political issues with regard to restricting proliferation cannot be reduced to technical questions relating solely to the availability of fuels or reactor technology. But it conveys an optimism about the ability of political institutions to cope with the problems that may, in practice, turn out to be equally overstated.

Perhaps this optimism is no greater than that with which President Carter swept into office three and half years ago, determined to demonstrate that controlling the hazards of nuclear power — or for that matter eliminating infringements of human rights — was little more than a question of political will. But such arguments were conceived in the calmer days of the mid-1970s, when the short-term stability of international relations made it possible to argue in terms of long-term strategies.

In the aftermath of Iran and Afghanistan, the climate has changed dramatically. Yet the irony is that, just at a time when the US is trying to restrain countries such as Pakistan and India from a rush to nuclear weapons, and arguing the need for effective international controls, it is engaged with other western nations in boosting its own nuclear arsenal.

Given this situation, it is difficult to see emerging the "Bargain of confidence" urged last month by a study group convened by the Royal Institute for International Affairs, with support from the Rockefeller Foundation. Indeed it is the reality of self-interest that needs to be addressed if we are to make genuine progress towards reducing the threat of nuclear war. Just as there are no technical fixes to the proliferation problem, so we should not be fooled into thinking there are any quick political fixes.

Doing what we can to raise the global standard of living, and reducing the tensions that flow from inequities in the distribution of wealth and power, will in the long run be the only way of removing the incentive for nuclear war. In the short term, efforts to conclude a comprehensive ban on the testing of new weapons, and to maintain pressure for arms limitation treaties such as SALT 2, would be a welcome show of good faith. A world built on conflicts and tensions — with or without fast breeders — can only encourage the instabilities that point to nuclear disaster. □

United Kingdom

Chemical company suppresses dioxin report

WORKERS exposed to 2,3,7,8-tetrachlorodibenzodioxin (dioxin), between 1968 and 1971, during manufacture of the herbicide 2,4,5-T, at the Derbyshire site of the UK company Coalite and Chemical Products Ltd, could face an increased risk of developing cardiovascular complaints, according to confidential documents in *Nature's* possession.

The documents — reports of detailed clinical and laboratory investigations on a number of dioxin-exposed workers at Coalite — suggest that the company has been falsely reassuring about the health of this particular sector of its workforce. According to a spokesperson for the Health and Safety Executive (HSE), the Executive also believes that the Coalite workforce has no long-term health problems. However, its view is based only on reassurances given by the company and not on a study of the medical reports which Coalite has not published and which the HSE is powerless, in law, to demand from the company because it no longer manufactures the product, 2,4,5-T.

Ironically, it was pressure from the HSE which forced Coalite to carry out the investigations in the first place shortly after the Séveso accident in 1976. Included in the study were 126 individuals, 41 of whom were known to have been exposed to dioxin, and showed symptoms of chloracne; 54 of whom might have been exposed to the chemical; and a supposed control group of 31. One of the studies compared the blood chemistry of the different groups. The author of the report of that study is Dr Jenny Martin, a lecturer in Occupational Medicine at the University of Manchester and a consultant chemical pathologist at Chesterfield Royal Hospital when the study was commissioned.

The results of that study show that the dioxin-exposed group has a greater incidence of impaired liver function as measured by the enzyme gamma-glutamyl transpeptidase. Furthermore when the results for serum cholesterol, triglyceride, high density lipoprotein etc were subjected to multivariate analysis — under the guidance of the Department of Probability and Statistics at the University of Sheffield — they showed a significant difference between the dioxin-exposed group and the controls. In the dioxin-exposed group, levels of serum cholesterol and triglyceride were higher and high density lipoprotein lower than in the controls. These are factors commonly held to imply an increased risk of cardiovascular disease.

None of this information is to be published, however. According to Martin, Coalite decided not to publish it on the

advice of Dr Kenneth Crow, a consultant dermatologist at St Margaret's Hospital, Swindon. She claims that Crow had told her that he had advised Coalite not to publish on the grounds that he was not happy with the statistics used in the report.

Crow, one of the world's leading authorities on chloracne, was involved in the treatment of such cases at Coalite. When approached by *Nature* to comment on the study, he said that he did not know which study was being referred to and that he would have to see it before he could comment. However, he strongly denies ever having advised Coalite not to publish the results of any study. *Nature* has approached Coalite for its side of the story, but with no success. Coalite stopped talking to journalists shortly after the Séveso accident in 1976.

Some related information, however, has been published. Instead of using an age and occupation-matched control group, Coalite chose to bolster the number of controls by including management staff undergoing a regular lipid screen at the time. When the study was commissioned, Martin was unaware of the composition of the three study groups. When she later learnt that the control groups had not been properly matched, she arranged to re-examine eight of the Coalite workers suffering from chloracne and to compare their blood chemistry with a matched control group.

The results of this second investigation, published in a letter to the *Lancet* (24 February, 1979, page 446), also show increased serum cholesterol and reduced serum high density lipoprotein in the dioxin-exposed group. The differences were considerably more marked than in the original, larger study. However, they were not statistically significant, a point which Martin notes, but says is simply due to the small numbers of subjects involved.

Perhaps the most extraordinary aspect of the story, however, concerns a burglary at Martin's house. Shortly after publishing her letter in the *Lancet*, Martin's house was broken into and the detailed medical records of the eight Coalite subjects were removed from her filing cabinet. Martin reported the theft to the local police constabulary but as she had no idea why anyone would want to steal this information the police investigation never got off the ground. A police spokesperson at Macclesfield confirms that the theft had been reported, that the case was not closed, but that as there was no clues about the motives for the theft, it was unlikely that it would ever be solved.

Martin told *Nature* that she had been

very distressed when she discovered the theft of the material for the second survey. She has no duplicate copy so the work is now lost.

She was surprised that *Nature* had obtained a copy of her original Coalite report, and having confirmed its authenticity said she was most unhappy that Coalite were not publishing the data. She said the company's decision was a major reason for her carrying out a second study and reporting it to the *Lancet*.

Coalite did, however, release an abbreviated form of the original report to one of the unions involved with the workforce at its Bolsover complex — the Association of Scientific Technical and Managerial Staffs. The abbreviated report is totally different from the original. In addition to its selective reporting, the union version says there were no statistically significant differences between the dioxin-exposed group and the controls, a statement which is quite untrue.

The most worrying aspect of this affair however, is the position of the HSE. The Executive has said that it is satisfied that the Coalite workers have not been unduly affected by their exposure to dioxin. Yet, if it has never seen the results of the clinical investigations, how can it express such a view? It says that it has to rely on the good faith of the company on this matter. According to an HSE spokesperson, when a product is no longer manufactured the Executive has no legal powers to demand medical records of workers. It is abundantly clear that if the Executive is to do its job properly it should have access to this information and should be given the legal powers to demand it. **Alastair Hay**

Unions want 2,4,5-T ban

THE UK Trades Union Congress has called for an immediate ban on the use of 2,4,5-T, pending a thorough investigation into its effects by the Health and Safety Executive. The National Union of Agricultural and Allied Workers has already advised members not to handle it. 2,4,5-T is widely used by the Forestry Commission in the UK, which has rejected such alternatives as manual or mechanical clearing as too costly. Two County Councils in England have also banned the pesticide.

The Ministry of Agriculture's Pesticides Advisory Committee has investigated 2,4,5-T eight times, and stuck to its conclusion that it is safe as long as handled in accordance with instructions. The TUC has condemned these enquiries as inadequate. □

United States

Patent law changes opposed in the Senate

ATTEMPTS to liberalise US patent laws by granting universities — and small businesses — exclusive rights to patents from federally-funded research have run into stiff opposition in the Senate on the grounds that they are selling out the American tax-payer.

Many leading research universities have campaigned actively in support of a bill, introduced by Senator Birch Bayh and Senator Robert Dole, which would grant such exclusive rights to any university or small business able to show that it is prepared to spend additional funds on encouraging the exploitation of the patent.

However, when the bill, which has been unanimously approved by the Senate Judiciary Committee, was introduced on the floor of the Senate last month, it ran into unexpectedly vehement opposition from Senator Russell Long, powerful chairman of the Finance Committee and long an opponent of apparent monopoly practices.

Senator Long threatened to filibuster the bill, hinting that this might place in jeopardy the progress of windfall profits legislation on the oil industry. The bill was quickly withdrawn from the debate by Senate leaders, worried that it might otherwise be lost, but is expected to be brought up again shortly.

Meanwhile Senator Long sent a letter to his Senate colleagues last week outlining his opposition to measures which he said represented a "radical and far-reaching giveaway" by the federal government, and would if passed "wipe out every law on the books which reserves for the public the paid results of [federally-financed] research".

Patent law revision has become one of the cornerstones of current attempts both within Congress and by the Carter administration to create an environment considered more conducive to technological innovation by private industry.

The Bayh Bill attracted over 50 co-sponsors when it reached the floor of the Senate. In speaking to the bill, Senator Bayh repeated a common complaint that although the government lacked the resources to develop and market products arising from federal research, it was unwilling to relinquish patent rights in a way that would encourage others to do so.

Similar arguments were heard from others in the debate. Senator Strom Thurmond pointed out that universities had successfully licensed 33% of the patents that they held, whereas 95% of the patents owned by the government had never been exploited. And Senator Edward Kennedy argued that, by helping raise the general level of economic competition, the legislation "would help America retain its

competitive edge in technology and innovation".

To refute charges that the government is selling out investments in research made by the US tax-payer, the bill contains a formula by which funds will be returned to the government from those inventions that eventually enjoy substantial success.

But this has not dampened Senator Long's opposition. In his letter to Senate colleagues he agrees that economic growth and increased productivity "require the most rapid dissemination of scientific and technological knowledge" — but argues

that allowing firms to file private patents would do the opposite by "bottling up" technical information.

In support he quotes Nobel Prize winner Wassily Leontief, Admiral Hyman Rickover, and Michael Pertschuk, Chairman of the Federal Trade Commission, who told a Senate committee in 1977 that there was no basis for claims that giving away title to private contractors promotes commercialisation of government-financed invention, and that the available evidence "shows the opposite". □

Third World research institute loses Congressional approval

THE Carter administration seems to have failed in its attempts to establish a new body to promote scientific and technological research efforts relevant to the needs of developing countries, known as the Institute for Scientific and Technological Cooperation (ISTC).

Delegates from the Senate and the House of Representatives, meeting last week to resolve differences of opinion over foreign aid spending in 1980, agreed to allocate \$12 million to the Agency for International Development (AID) to support programmes of scientific and technical cooperation — but rejected the proposal to establish a new institute to carry out such programmes.

Thus although the institute legally came into existence last October, following agreement between the two legislative bodies on authorising legislation, all of its activities will now be incorporated within AID, with responsibilities that were to have been delegated by Congress to the director of the ISTC now being assumed by the administrator of AID.

The rejection of the ISTC by Congress, which seems inevitable even though the conference report could theoretically be objected to by either House, is a major blow to the administration, particularly since the institute figured prominently in the US presentation to the United Nations Conference on Science and Technology for development in Vienna last August.

From the beginning, administration officials have argued that the new institute, plans for which were first announced by President Carter in a speech in Caracas in 1978, would not be acceptable to Congress if it was run by a totally independent board — an alternative proposal actively canvassed by some scientists — but that a new body operating under the broad umbrella of AID should be acceptable.

Many in Congress have not been

convinced by the arguments for a new institute. In particular, Senator Peter Deconcini last summer persuaded the Senate to reject authorisation plans for the institute on the grounds that it would create unnecessary additional bureaucracy.

This decision was reversed in meetings with the House of Representatives on the authorising legislation. But Senator Deconcini used the same argument last October to persuade the Senate to cut off funds for the institute, and this time his arguments prevailed in conference, although House delegates managed to argue the extra money for the AID budget.

Administration officials are debating whether, now ISTC has been authorised but not funded, they should push ahead for the \$95 million requested for the institute in the 1981 request. But such a move could jeopardise the \$15 million requested for the new Science and Technology Fund being set up by the United Nations Development Programme, which has already been cut back to \$10 million by a House subcommittee.

Those who have been following the changing fortunes of the ISTC in Washington last week expressed disappointment, but little surprise, at the outcome, since the debate over the institute has become bogged down in a political climate increasingly unsympathetic to providing assistance to Third World countries.

However some now feel that the time may be ripe for other initiatives. The National Science Foundation, for example, has recently announced a new programme to encourage US universities to establish links with Third World research groups. Others are suggesting that private foundations might be persuaded to support a scaled-down version of the original ISTC proposal.

David Dickson

International exchange

Hamburg forum a success — of a kind

"It was a success. All twenty speakers at the closing session agreed that it was a success. The fact that everyone stayed and there is a final statement is a sign of success".

Such was the summing up of the executive secretary, Dr Klaus Gottstein to *Nature*, when, after two weeks work and a marathon all-night session that ran on past the official closing date, the Hamburg Scientific Forum managed to hammer out a final statement that was more than diplomatic lip-service to peace and détente.

For in addition to noting that since the signing of the Helsinki Final Act there had been a "significant expansion of scientific cooperation . . . greater in some areas than in others", observing that "different levels of scientific development . . . should be taken into account when planning scientific cooperation", and laying the foundations for convening a further forum in the future, the final statement contained three proposals on subjects which had been the focus of controversy throughout: human rights, the international training of young scientists, and the freedom of scientific exchange and communications.

While there was no reference to Sakharov in the final statement — although the US delegate did raise the issue again in his closing address — the human rights issue did find a place there in general terms.

Increased scientific cooperation, said the statement, can only be achieved "by respect for all the principles and by full implementation of the relevant provisions of the Final Act. All participating states are therefore urged to observe the spirit and the letter of the Final Act, particularly with respect to the conditions essential for scientific cooperation."

"It is furthermore considered necessary to state that respect for human rights and fundamental freedoms by all states represents one of the foundations for a significant improvement of these mutual relations and of international cooperation at all levels."

One subject which the Yugoslav delegate, Dr Drago Ocepek, had earlier associated with human rights was the international training of young scientists. Several delegates had endorsed this theme, including Dr Helge Gyllenberg of Finland and Dr J J Went of the Netherlands. This approach, however, is not popular with the Soviet Union, which tends to view visits abroad as a reward for achievement rather than a stimulus to further effort. Indeed, throughout the two weeks, the Soviet delegates had shown a marked reluctance to discuss any practical details of the logistics of exchange, claiming that the agenda should be confined to professional

discussions on the selected subjects — energy, urbanisation, food production and cancer, cardiovascular and virus diseases.

Nevertheless, international "training courses for young scientists . . . that would enable them to study new science and methods for shorter or longer periods" found a place in the final statement, with the recommendation that "information about these facilities . . . should be disseminated as widely as possible".

The other major barrier to international exchange — restrictions on the free circulation of scientists and information had also produced vigorous confrontations. There were the routine complaints about Soviet scientists who fail to arrive at conferences where they are scheduled to speak — countered,

somewhat irrelevantly, by an accusation from the Soviet Union that in 1976 the University of Geneva had refused to let an Iranian "assistant" in the law department deliver lectures in Marxism. Full freedom of exchange, said the Soviet and East German delegates, was only possible in conditions of complete disarmament.

From the Danish delegation, Dr Maaloe had described the work of the ICSU Committee on the Safeguard of the Pursuit of Science, and stressed the scientific and economic losses caused by unnecessary secrecy. All this was condensed in the final statement to a clause urging "equitable opportunities for scientific research and for wider communications and travel necessary for professional purposes".

Vera Rich

US academy suspends exchanges with Soviet Union

THE council of the National Academy of Sciences has voted to suspend for a period of six months all bilateral symposia, seminars, workshops and new initiatives with the Soviet Academy of Sciences, in protest at the internal exile from Moscow of physicist Dr Andrei Sakharov.

The first meeting to be affected by the academy's decision will be a conference on the interactions between laser beams and matter which was to have taken place at the University of Arizona in early March, and to which 20 Americans and 15 Soviet scientists had been invited.

Three other meetings over the next six months will also be affected, including meetings between scientists from both sides

on basic research, on physics and on experimental psychology. However the council has stressed that its decision is not meant to affect individual contact between US and Soviet scientists, which it says "are matters properly left to the consciences of the participating individuals".

The academy's decision was agreed by a vote of 10 to 3, although some of those who voted against are thought to have pushed for firmer measures, such as extending the suspension of exchanges to one year.

In a telegram sent after the council's meeting to Academician A P Aleksandrov, President of the Soviet Academy of Sciences, Dr Saunders MacLane, Vice-President and acting chairman of the NAS council expresses "our profound hope that the safety and freedom of movement of academician Andrei D Sakharov and his family will be protected".

Dr MacLane also says that the policy adopted by the council — which has been organising exchanges with the Soviet Union for 21 years — reflects the strongly held views of many US scientists. "Our council hopes that the circumstances that have led to the adoption of that policy will soon change so as to permit restoration of the full exchange programme which we have, until recently, viewed with great satisfaction".

The council adds that it sees "no long term national benefit in modifying scientific exchanges to every political action and reaction", but that it is taking action following repeated requests from its members. Dr Sakharov was made a foreign associate of the academy in 1973.

David Dickson

United Kingdom

London medical colleges for the chop

THE Westminster Medical School, and the pre-clinical courses at King's College and the Royal Free Hospital should close, according to a London University working party whose report was published last week. In addition the British Postgraduate Medical Federation would be disbanded and five of its smaller institutes would lose their separate identities. Chaired by Lord Flowers, the committee was charged with rationalising expenditure on medical education in the university while retaining student numbers and staff.

Savings of £6 million a year would result, says the report: £1 million on maintenance of the premises to be vacated; £1 million on administration; £1 million on academic services; and a further £3 million "from the eventual rationalisation of academic departments and academic posts". The present cost of the schools to the university is some £51 million a year. The savings would be redistributed among the remaining medical schools.

In terms of research, the principal casualty of Flower's proposal would probably be King's College — one of only two schools in the university (the other in University College) to operate its pre-clinical teaching on a multi-faculty university campus rather than in a hospital.

"Research is not threatened directly" says Peter Baker, professor of physiology at King's, who estimates that King's receives 24% of all the Medical Research Council and Science Research Council grants for pre-clinical science subjects to the University of London Medical Schools. But if King's loses its medical students, staff members are likely to be reduced and their research with it.

Lord Flowers: finding a way to rationalise expenditure.

Baker feels that the working party has been unduly influenced by a desire to bring pre-clinical teaching within hospitals, in direct opposition to the recommendations of the Royal Commission on Medical Education (the Todd report of 1965) — which stressed the need for a broader-based, multi-faculty organisation for medical teaching.

The battle lines are drawn, Baker believes, between the medical profession which would like to see students exposed to hospital life as early as possible, and the scientists who believe that a medical student requires a thorough grounding in scientific method. Also at stake, says Baker, may be the money involved in pre-clinical education — twice the amount spent on the clinical phase.

When clinical and pre-clinical education are combined 'vertically' within a teaching hospital, says Baker, with the division of funds controlled by hospital committees, "clinicians are very effective in giving the pre-clinicians little money". Pre-clinicians were not represented on the Flowers committee, Baker notes.

The report will be considered by the university for a decision in July. □

High Energy Physics

LEP by 1986?

THE Large Electron-Positron collider, LEP, could produce its first beam by 1986 — three years ahead of the original target, the European Organisation for Subnuclear Physics, CERN, is expected to announce later this week. A Committee of Council meeting last Friday approved this advanced programme, although CERN member states have not yet received a formal proposal.

If CERN members are favourable, there could be a decision within a year to build LEP — while keeping to a 'constant' budget. Pressure from the Italian delegation, plus the prospect of competition from the United States have led to CERN's new sense of urgency.

The attitude of Professor Herwig Schopper, who is likely to be elected CERN's next director-general in June, may also have contributed. Professor Schopper told *Nature* recently that LEP could be built within five years of a positive decision, "but we will have to cut out all the frills". The minimum 'one-sixth' LEP defined in earlier CERN designs could be trimmed, thinks Schopper, to a 'budget-LEP' without changing the size of the tunnel or compromising the chase for the intermediate vector boson. "Building electron accelerators is very different from building proton accelerators" he says. "In our last accelerator at DESY [PETRA] most of our calculations were proved wrong. It will be the same with LEP."

Building LEP will thus be an experiment. Sophisticated orbit correction mechanisms should be built when needed rather than designed *a priori*. Financial savings could also be found in the experimental halls. **Robert Walgate**

ARMS proposes security for 60% of untenured researchers

THE UK Association of Researchers in Medical Science has prepared a document showing that 60% of present contract workers could be placed in tenured career tracks with no additional expenditure and no reduction in the workforce. The plan calls for the creation of a pool of tenured researchers to be funded out of the £81.5 million now used to support contract work by five main sources; the MRC (£24.8 million), the Department of Health and Social Services (£18.3 million), charities and trusts (£22 million), pharmaceutical companies (£11.9 million) and the Royal Society (£4.5 million). ARMS proposes the creation of research institutes based at

universities or medical schools typically employing 85 researchers, 50 of whom would be on tenured tracks and 35 post-doc. The cost per institution would be £1.29 million per year based on an average salary of £9,000 plus 25% for pension and insurance plus £2,500 running expenses plus a 10% institutional surcharge.

Surveys of three industrial laboratories show that total running costs of a research establishment of 2000 employees averages £20 million a year, a figure that compares favourably with ARMS' estimates. The total cost of the ARMS scheme nationally for the estimated 4500 researchers currently employed on short term contracts

would be £68 million. The proposed 10% institutional surcharge would be used to build up an operating fund for tenured researchers out of the estimated £26 million currently supplied by charities and trusts who cannot commit their money on a long term basis.

Representatives from ARMS discussed the proposal last week with Professor James Gowans, Secretary of the Medical Research Council who requested that it be taken to the universities first for their reactions. Gowans told *Nature* that "ARMS is writing to the wrong address. If they get a deal from the universities then I'll have a look at it". **Joe Schwartz**

NEWS IN BRIEF

Spanish science lurches ahead

SPANISH scientists have raced feverishly to meet a 1 March deadline for applications for newly released research funds. Announced in mid-January by the Comisión Asesora de Investigación Científica y Técnica, the amount of 1600 million pesetas (£10.6 million) is the first money made available to researchers since 1977. In addition the commission announced the formation of a committee of 20 to map out future Spanish research strategy. Researchers fear that the committee may impose a straightjacket on the fragile state of basic research out of an inability to realistically assess what kind of research is in "the national interest". A three year plan for restructuring research backed by 50 billion pesetas (£350m) will be tabled in the parliament this Spring.

Canadian research threatened

THE Science Council of Canada has warned that threats to the quality of Canadian higher education, where university enrolment is currently decreasing even though the number of 18-24 year olds is increasing, could have a severe impact on the future strength of Canadian research.

The report* says that for the past ten years, the financial resources for teaching and research provided by both the provinces and the federal government have generally been less than sufficient to keep up with inflation, leading to the serious erosion of research facilities built up in the 1960s.

It says that in addition to seeking more money, universities will have to make a number of hard decisions. These include the elimination of courses and programmes where the number of students and the resources for teaching or research are inadequate for productive scholarship of the highest quality; the transfer of faculty and facilities to other universities; the consolidation of graduate work in specific disciplines into joint centres embracing more than one university; and the common use of major facilities.

**University Research in Jeopardy: The Threat of Declining Enrolment. Available from the Canadian Government Publishing Centre, Supply and Services Canada, Hull, Quebec.*

Pharmaceutical company to rent space at Yale

MILES Laboratories Inc, a subsidiary of the West German chemical and pharmaceutical company Bayer AG, is to rent space in a building allocated to Yale University's department of biology to

establish an institute for pre-clinical pharmacology.

Initially seven or eight scientists and technicians are expected to work on the research and development of new pharmaceuticals, primarily in the cardiovascular field, in a section of Yale's Osborn Memorial Laboratories, which the company has agreed to renovate as part of its payment to the university.

"This agreement is especially significant for the basic biological sciences, since close ties with industry have not existed previously at Yale," Dr Frank R. Ruddle, professor of biology and human genetics, and chairman of the biology department, said in announcing the agreement. "Because of new technical and theoretical developments in biology, we believe that such relationships will be mutually beneficial and therefore more common in the future."

Stanford announces new centre for electronics

THE University of Stanford has announced plans for a new Center for Integrated Systems, bringing together in a single research laboratory individuals with experience in physics, materials science, electrical engineering and computer research to work on very large scale integrated systems (VLSI) for industry and business management.

"Our goal is to make Stanford the premier centre in the world for VLSI research" said Dr James F Gibbons, professor of electrical engineering, in announcing plans for the \$15 million centre.

The three goals of the new centre are: to produce approximately 100 MSc and 300 PhD graduates per year ("tomorrow's technological leaders" according to Professor James Meindl); to promote research, including the development of working design automation capability and computer-managed fabrication facilities; and to offer, via instructional television and videotapes, new courses, conference and workshops "designed to keep scientists and engineers now employed in industry abreast of rapid developments in the field." Funding will come principally from government and industry sources.

Fusion beam injection success

SCIENTISTS at the University of California's Lawrence Berkeley Laboratory last week reported that they have successfully tested a neutral beam injection system which will be used to heat the plasma of the Tokamak Fusion Test Reactor at Princeton Plasma Physics Laboratory, due to start operating in December 1981.

According to Dr Kenow H. Lou, project manager for the injection system at LBL, deuterium beams were successfully accelerated to 120,000 electron-volts, producing seven million watts of power in pulses lasting 0.5 seconds. The team is now studying ways of increasing the duration of the beam to 1.5 seconds.

The Princeton Tokamak will use four such neutral beam injection systems, the prototype of which has been built as a collaborative effort between LBL and the Lawrence Livermore Laboratory, which carried out the beam line engineering. Following the successful tests — described as a "major milestone" in the US fusion energy programme — the prototype system will remain in operation to develop further information and experience which may affect TFTR operations.

UK short of basic grade nuclear inspectors

THE Nuclear Installations Inspectorate is 53% below its full complement of basic grade inspectors according to information released last week by the Department of Employment. In answer to a parliamentary question by Frank Hooley (Labour, Sheffield) the department revealed that the NII was having difficulty recruiting structural, electrical, mechanical and instrumentation engineers and has a shortfall of 14 out of its complement of 26 positions. A Health and Safety Executive official told *Nature* that routine work was not affected but that in the review of the pressurised water reactor specific areas of work might have to be subcontracted to the Safety and Reliability Board of the UK Atomic Energy Authority. The 61 principal inspectors and 26 inspectors of the NII are responsible for surveillance of 11 nuclear power stations, three radio-chemical centres, five nuclear fuel production works and the UKAEA's facilities at Windscale, Dounreay, Springfields, Winfrith, and Harwell.

CERN opens data transmission experiment

THE European STELLA experiment to transmit scientific data by satellite between sub-nuclear physics laboratories was initiated today in Geneva. Directors-General of the European centre for nuclear research, CERN, the Internal Market and Industrial Affairs Commission of the European Communities and the European Space Agency took part in a ceremony inaugurating fast and reliable data transmission between CERN and laboratories in Hamburg, Saclay, Oxford, Pisa, Dublin and Graz. The STELLA system will transmit data at 1 megabit per second using the European telecommunications satellite OTS-2.

No technical fix to a political problem

THE International Nuclear Fuel Cycle Evaluation ended on 29 February with a plenary session that adopted the reports of all the study groups. **Hermann Bondi** (right) Chief Scientist at the UK Department of Energy and leader of the British delegation to INFCE, assesses its work

THE INFCE reports naturally reflect many points of view, yet they were unanimously agreed. Some countries had suggested 'technical fixes'; some claimed that energy independence was necessary, and that the whole argument about non-proliferation was just a device to keep a vital new technology firmly confined to the most advanced states. But it was agreed that there is no technical fix to the political problem of proliferation. There is no fuel cycle that presents no such risks and dangers. On the other hand the working groups looked closely at the sensitive areas; how they could be made less risky, what could be done to improve their security, and what institutional measures could be evolved which would further increase international re-assurance.

I concentrate on four areas: the availability of nuclear fuel, the economics of the fuel cycles, the risks of proliferation, and the terms and conditions of nuclear supply agreements. Safety and environmental questions were not addressed in any great detail.

INFCE assumes a fairly high rate of growth in nuclear generating capacity. Compared with about 125 GW of capacity today, INFCE projects 850 to 1200 GW in

the non-Communist world in 2000, and 1800 to 3900 GW in 2025. With use of the once-through cycle and on its high projection of growth, INFCE concludes that the lifetime uranium requirements of the reactors installed and in operation by 2000 will approach current estimates of known uranium resources (5 mTU). These figures have been criticised, notably in the US, for being unduly pessimistic about uranium availability.

But the figures are not everything. INFCE rightly stressed that the uncertainties in these forecasts are great — not just in the prediction of nuclear demand and of the extent and accessibility of geological reserves of uranium. The uncertainties in the political availability of uranium are greater perhaps than for any other commodity. The message is simple. If countries are to be confident that there will be enough uranium to fuel their reactors over the next 30 to 40 years, acceptable solutions to political and environmental problems limiting the exploitation of uranium must be found, new sources of uranium must be discovered and brought into production, and reactor strategies that conserve uranium must be adopted by at least some of the big users.

The scope for new discoveries of uranium is good. Estimates range from 6.6 to 14.8 mTU. If these resources can be discovered, brought into production, and the uranium made available internationally, supply should meet the requirements of INFCE's perhaps more realistic low projection of nuclear growth to beyond 2025. But the extent to which this will happen is uncertain. The more pessimistic a country, and the more dependent it is on uranium imports, the more likely it is to want to move to the early introduction of reactors that conserve uranium, such as advanced thermal reactors and fast reactors.

Fast reactors offer the prospect of nuclear development eventually almost free from uranium supply constraints. So while INFCE does not say that the early introduction of fast reactors is essential on resource grounds, it does illustrate the impact of decisions about reactor strategy — and their timing — on uranium supply and demand. Such decisions, like many in energy policy, depend largely on a country's perception of its need to be

insured against uncertainties in fuel supplies.

In discussions on the economic aspects of the fuel cycles it became clear that considerations vary from country to country. No fuel cycle can be said to have a universal economic advantage over the next few decades. Recycle into light water reactors is of only minor economic advantage, but may offer the benefits of reducing reliance on imported uranium. On the other hand, if the capital and fuel cycle costs of fast reactors can be brought down, fast reactor recycle could offer considerable advantages.

INFCE came to no definite conclusion on when the fast reactor would compete economically with thermal reactors. The uncertainties in the future price of uranium and of fast reactors, and regional variations in uranium supply, mean that countries will take different views about when to proceed from thermal to fast reactors.

Much of INFCE's discussion centred on two related subjects: how the risk and the fear of weapons proliferation can be reduced, and how to make nuclear energy widely and assuredly available.

From the start it was recognised that a decision to construct nuclear weapons is political, and that the misuse of the civil fuel cycle is not the easiest or cheapest route to acquiring them. INFCE was a technical, not a political evaluation. The reports, therefore, look only at the way in which a civil nuclear programme might help a country make a nuclear explosive.

The misuse of fuel cycles that involve the handling of large quantities of weapons-usable material — not just plutonium, but highly enriched uranium (HEU) or uranium 233 — might offer a path. But discussions in the Working Groups and in the TCC showed that comparisons between the proliferation risks of the various fuel cycles were extremely complex. How, for example, does one assess the relative proliferation

Background and participants

INFCE was set up in Washington in October 1977, in response to heated disagreements between states over the nuclear fuel and technology trade. In particular, President Carter had aroused anxiety among developing nations in April that year when he called a halt to the separation and use of plutonium, implying the deferral of reprocessing and confinement to a once-through cycle.

Sixty-six countries took part in the discussions; industrialised and developing; weapons and non-weapons states; East and West; nuclear suppliers and customers; those that had signed the Non-Proliferation Treaty and those that had not. Five international organisations also took part. The Evaluation was not, however, a negotiation. The Organising Conference set up eight working groups, linked by a Technical Co-ordinating Committee.

Refuelling the UK's Prototype Fast Reactor at Dounreay, Scotland. Facilitating supply of this fuel (plutonium oxide) without risking weapons proliferation was one of INFCE's major concerns

risks of the various fuel cycles were extremely complex. How, for example, does one assess the relative proliferation risk of an enrichment plant, which produces HEU for a research reactor, with that presented by spent fuel (which necessarily contains plutonium) stored in ponds where it becomes increasingly accessible as its radioactivity decreases?

INFCE concludes that the proliferation risks of fuel cycles cannot be compared in the abstract, but depend on the specific arrangements. No single judgement about the relative risks of proliferation can be made which will be universally and permanently valid. The reports look at those fuel cycle activities that are sensitive and concentrate on measures to reduce the risks of proliferation arising from them.

INFCE examines the various technical options for reducing the proliferation risks of the back end of the fuel cycle. Measures to reduce the presence of weapons-usable material in separated form in the fuel cycle, such as the co-conversion of the uranium and plutonium solutions produced at reprocessing plants directly into mixed oxide; measures to use radioactivity to protect these materials from diversion, for instance, by spiking fuel with high energy gamma emitters; and measures to protect them by the use of physical barriers, such as providing extra containment around reprocessing plants.

Measures using radioactivity as a protective barrier not only involve considerable environmental and economic penalties, but also make safeguards more difficult because of the material accountancy problems created by the intense radiation. The other measures, though perhaps desirable for future plants, turn out by themselves to have only a limited influence on proliferation risks.

INFCE thus could not identify any

potential technical fixes in this field, but stressed that research reactors could and should be converted to require only uranium of low enrichment. This was the only useful technical measure emerging from a full discussion of the proliferation risks arising so seriously in enrichment.

More promising are institutional measures. Multinational fuel cycle ventures can offer a country seeking fuel cycle services a more economic way of meeting their needs, and are a potentially useful measure for reducing proliferation risks. INFCE points that a first step towards such institutional arrangements would be for countries with large fuel cycle facilities to offer services to others. This would help postpone the need for the latter to build their own fuel cycle facilities.

But perhaps the most promising institutional measure is a scheme for international plutonium storage so that plutonium was only stored under international supervision and released solely for safeguarded peaceful uses. This could have important non-proliferation advantages and INFCE applauds the work being done in the International Atomic Energy Agency to establish such a scheme.

The central feature of the non-proliferation regime, however, is the network of agreements, generally implemented by the IAEA by which states accept the international system of inspection or "safeguards" on their nuclear activities. INFCE sees no problems with the techniques applied to existing operating plants, but foresees an important need for development work on the techniques for safeguarding plants handling large quantities of weapons-usable material. A crucial point is the need for security objectives to be considered at the design stage of any plant.

One thing, however, that INFCE does

not go into is how to win wider acceptance of safeguards, mainly because this is a political question not in INFCE's remit. But there is an area of INFCE's work which may provide part of the answer. Working Group 3 was devoted to the question of how to improve "assurances of supply" — assurances that once a nuclear supply contract has been signed, neither government will interfere in its performance. In recent years some suppliers, notably the US and Canada, because of growing worries about proliferation, have cut off previously agreed supplies. This has reduced the credibility of such arrangements, and has tended to make customers more determined to make themselves self-sufficient in nuclear supplies and services in the long run.

Working Group 3 has looked at the way in which suppliers can be given confidence that their non-proliferation concerns can be met, while at the same time giving customers the confidence that their supplies will not be interrupted. This is the central theme of non-proliferation policy, and the strength of feeling among the developing and other customer countries about their need for nuclear energy makes its solution of crucial importance. Working Group 3 suggests that a consensus on the non-proliferation conditions of supply could first be expressed in "common approaches" to bilateral agreements, which might later evolve into a more formal multilateral agreement on the terms and conditions of nuclear trade. These ideas should be followed up, and the IAEA offers an ideal forum for doing so.

The findings of INFCE do not reflect only the views of a few large industrialised nuclear countries. The Evaluation has respected the views of the countries with small nuclear programmes, the customer and developing countries.

Looking at the resource arguments, it describes the reasons why countries wish to keep open the option of plutonium recycle. Looking at the economic arguments, it shows why many countries look ahead to fast reactors so as to extract the maximum energy value from limited uranium resources. Looking at non-proliferation questions, it shows how pointing accusing fingers at different fuel cycles or seeking alternatives can uselessly divert attention from the more fruitful task of improving safeguards and creating suitable institutions. And finally, it suggests how work towards an improved consensus on the conditions of nuclear trade would both promote the aims of non-proliferation and help ensure that nuclear energy is available to meet the world's energy requirements.

It is a triumph of common sense and of common purpose that the very wide cross section of countries represented in INFCE, created by the US initiative, could arrive at this consensus, which while in no way underwriting the original American specific measures, points a way forward. □

Europe embraces the fast breeder reactor

The International Nuclear Fuel Cycle Evaluation has given a boost to the fast breeder reactor. But while the US is rejecting the breeder, others are embracing it, writes **Robert Walgate**

FRANCE'S fast breeder programme is already many years ahead of any other nation's. Last week Electricité de France announced an order for a further two fast reactors of 1500 MW each to supplement Super-Phenix, a commercial demonstration reactor due to produce electricity in 1983, so confirming the French lead.

But while France may be ahead in practice, other European countries are with her in spirit. Last month the Council of Foreign ministers of the nine-nation European Community drafted a resolution urging member states which have fast breeder programmes to "get on with them", and offering "appropriate" EEC support. Already, Euratom loans are available to countries developing fast breeders.

Moreover, the Assembly of the Council of Europe, a loose association of 18 European states, recently adopted a resolution that "current programmes in Europe for the development of fast breeder technology to the point of commercial-sized demonstration plants should be continued".

Dr Walter Marshall, Deputy Chairman of the United Kingdom Atomic Energy Authority, and a prominent member of INFCE, argued last week that countries with an advanced nuclear programme, such as those of Europe, should concentrate on fast breeders, leaving

thermal reactors to other countries.

Dr Marshall, who once described INFCE as "an exercise in proliferation" because it would help communicate sensitive technologies from the most to the least nuclear of its 66 participants, said that such a regime "would not guarantee the non-proliferation of nuclear weapons . . . but it does give the maximum opportunity to governments . . . to secure the most proliferation-resistant regime possible."

Last week the UK House of Lords debated the fast breeder issue, prompted by the Council of Europe resolution. Viscount Thurso, whose fief includes the Dounreay prototype fast reactor, compared progress.

"Our own PFR deliberately contains fuel elements of commercial size such as will be used in a commercial demonstration fast reactor, and employs boiler and coolant pump designs of a commercial sort which will only have to be scaled up slightly for CDFR. Super-Phenix will have to use fuel elements and boilers of designs hitherto untested in practice, and will in consequence have a fairly large question mark hanging over it."

In the US "EBRII is still running but FFTF is doing criticality tests only and work on CFBR has stopped . . . The state of progress in Russia indicates that BN600 is not yet critical and may not be operational until 1983 and although they are preparing to start on BN1600, they have a long way to go with its design, especially in the field of fuel technology."

In Japan "where they very much need atomic energy . . . they are very far behind schedule. Monju, scheduled for operation in 1986, is not yet in building and it is only the equivalent of our PFR."

"In Germany, the KNK11, is only a converted thermal reactor and SNR300 is delayed by legislation; SNR2 is only a gleam in their eye. In France alone is progress being maintained, although in my view they are behind us in fuel element and boiler design and have an unproved fuel cycle."

Britain should thus move rapidly to the promised public enquiry on the CDFR, argued the Viscount, and in this he was supported by most speakers. Only two strong voices were raised against — those of Lord Avebury, an engineer and a Liberal, and Lord Bowden, an ex-Secretary of State for Education and Science.

Lord Avebury welcomed the debate not because of the immediate need for the fast breeder but "as a warning of the powerful onslaught which is to be expected from the

nuclear lobby if, and when, the government initiate the public inquiry".

"I think that the adoption of breeder technology, plus the reprocessing of the spent fuel from thermal reactors, which of course involves the separation of plutonium, would mean that by the middle of the next century . . . there would be 25 or 30 nations with at least a primitive weapons capability."

And Lord Bowden questioned the economics of the reactors. "No-one can be found to deny that a fast breeder reactor will cost very much more than a conventional type. The ratio has been variously estimated at five times. The Germans have found that their own estimated cost has escalated ten times since they first started on the work."

The price of uranium must rise dramatically, said Lord Avebury, if the fast reactor was to be economic — perhaps from its present level of \$40 per pound to \$218 per pound, according to a study prepared by the US Arms Control and Disarmament Agency. But at these prices, argued Lord Bowden, there would be an increase in the size of economic uranium by a substantial factor, perhaps sufficient to equal the maximum breeding factor attainable in a fast reactor.

This breeding factor (the energy obtainable per pound of uranium in a fast breeder as compared with a thermal reactor cycle) "will be less than a dozen times in practice on any system which has so far been proposed and worked out in detail" and not the theoretical factor of 70 commonly quoted. "The Americans are very shrewd in their assessment of economic potential" said Lord Bowden "and they have decided there is no case for developing the fast breeder for several years to come . . . So I am afraid that if we go ahead with the fast breeder in Europe we shall repeat almost precisely the story of Concorde: it will be a technical triumph and an economic catastrophe."

Lord Bowden urged the government instead to consider the Canadian CANDU reactors "which get three of four times as much power per tonne of uranium" as pressurised water or advanced gas-cooled reactors as a way of conserving uranium. "The amount of power we shall in practice get from fast breeders is nowhere near the theoretical amount postulated. It will almost certainly take at least 20 years before the fast breeder can double the amount of fissile material it has to start with. It will take several tonnes of plutonium to start off a fast breeder and, when it has been started, the plutonium and the blanket have to be taken out and reprocessed chemically many, many times."

"I beg the government" said Lord Bowden "to consider this as an alternative". □

● **Maurice Bazin reports from Rio de Janeiro on the Brazilian response to INFCE.**

The response is one of relief and diplomatic excitement. The controversial multi-billion dollar nuclear agreement with West Germany, signed in 1975, which envisages the construction of up to eight plants of 1,200 MW by 1990, accompanied by uranium enrichment and fuel reprocessing facilities, remains unaffected.

"There was a consensus at the meeting that its conclusions will have no moratorium effect on our nuclear programme and will not serve as a pretext for modifying existing treaties" declared Hervaldo de Carvalho, director of the National Commission for Nuclear Energy (CNEN) who attended the INFCE sessions. "The results will be distributed among all countries without discrimination, but no country will be forced to take special measures as a result of the technical exercises carried out by INFCE."

CORRESPONDENCE

Dioxin, an emotive word

SIR, — The tragic murder of the production director of the trichlorophenol plant in Séveso demonstrates most dramatically that “dioxin” has joined a select group of words including “cancer” “nuclear” and “fluoride” which inspire fear and trigger emotions that require the explanations of psychologists not a chemist.

The ease with which traditional standards of rigour in proof can be abandoned when discussing toxicity should be a warning to all serious scientists. The article by David Dickson (31 January, page 418) can do nothing but reinforce the almost mediaeval atmosphere of mystic suspicion which seems to have enveloped this subject.

Pentachlorophenol is probably not one of the most widespread pesticidal chemicals in domestic use in the United Kingdom, other chlorophenols used in disinfectants could perhaps claim that honour, but it is quite widely used as a wood preservative and particularly in the United States. It has been used for more than forty years, and long before the present emphasis on worker safety, so that a very large number of workers have been exposed to considerably greater dosages than any relevant to the “cases” quoted in the article. There is no suggestion that the handling of pentachlorophenol-based wood preservatives, nor even pentachlorophenol itself, has been a major health hazard to operatives in the industry.

Surely if a material utilised at extremely low concentrations in contact with a consumer were to give rise to such dramatic hazards, then we could look for a large number of fatalities or significant debility in workers in the industry. This is simply not the case.

It is important to stress that the most toxic dioxin — tetrachlorodibenz-p-dioxin, has never been found in industrial pentachlorophenol (of modern manufacture) and the accuracy of analysis is now at a confidence level of one part in ten million.

Octachlorodibenz-p-dioxin, which is a known contaminant, is less toxic than pentachlorophenol itself. To claim that little is known of the physical and chemical toxicological properties of other dioxins is unfair, and perhaps the interested reader should refer to “*Pentachlorophenol Chemistry, Pharmacology and Environmental Toxicology*”, editor K. Tanga Rao, “*Chlordioxins — Origins and Fate*” by Ethyl H. Blair, and “*Dioxin — Toxicological and Chemical Aspects*”, edited by Flaminio Cattabeni, Aldo Cavalario, Giovanni Gallis. The hexachlorodioxins, which are found in technical pentachlorophenol of the quality now available in Europe, are at a level of about five parts per million, and the most toxic isomers are at proportionately lower levels. Their chronic toxicity is well established and it would be necessary to take more than the lethal dose of technical pentachlorophenol regularly in order to run the risk of future development of cancer. In effect the acute toxicity of pentachlorophenol protects against long term hazard.

The approach of certain environmentalists and American attorneys seems to centre on contaminants, even if present in extremely small quantities overlooking the accepted acute toxicity of the main ingredients. Furthermore they seem to believe that pentachlorophenol is applied in isolation and disregard co-solvents, solvents, carriers, resins, pigments and dyes, all of which form part of preservative formulations, the majority of which will certainly not have been

investigated for impurities nor their toxicology determined with anything approaching the thoroughness applied to pentachlorophenol. Nor is any mention made of the potential hazards to man of the organisms which pentachlorophenol controls.

Your readers can be assured that there is no iceberg, the divers have been down these many years and would have found it. Can I plead that we remember that all chemicals are toxic, it is only a matter of determining the dose?

Finally, I revert to my opening remark, can any psychologist offer an explanation of this fear and the profound emotions it releases?

Yours faithfully,

J. DAVID

Hertfordshire, UK.

World energy needs of the future

SIR, — R.B. Temple, in a letter (7 February, page 520) virtually as long as my (necessarily limited) review of *World Energy — Looking Ahead to 2020* (15 November, page 344), says many things I would readily endorse.

It is for the reader to judge whether I was sufficiently critical of the energy strategy proposed by the Conservation Commission of the World Energy Conference. My emphasising, through direct quotation as a form of shorthand, of the Commission's conclusion that their assessment required “doubling nuclear power plant capacity every six years”, was indeed meant to signal the reader to the far-fetched numbers this implied and which Dr Temple has calculated. No disagreement here, whatsoever, especially as the latest official UK estimates of new reactor capital costs are nearer £1000/kW, or £1 × 10⁹ for a 1000 MWe plant.

As for my own position in the energy debate, I would suggest an examination of Chapter 5 of *World Futures — The Great Debate* (ed C. Freeman and M. Jahoda), Martin Robertson, Oxford, 1978 which was reviewed by Lord Ashby in *Nature*, (November 9, 1978, page 144). I suspect Dr Temple and I would share much common ground.

Yours faithfully,

J. H. CHESHIRE

Science Policy Research Unit, University of
Sussex, UK

Nuclear energy and the world economy

SIR, — R.B. Temple, who wrote a letter in your 7 February issue (page 520) commenting on the problem of feeding world economy with nuclear energy has been trapped in a famous pitfall, which is to assume that the size of a certain machine, in the particular case that of a nuclear reactor, is God given and time invariant.

Now, if we analyse energy systems or transportation, or chemical ones, we find that there exists a very tight link between the size of a plant and that of the market, in most cases the link being that of simple proportionality. So, if one increases electricity consumption by say a factor of 1000, which happened for example in the US from the beginning of the century to present, the number of power

stations stays constant (or more precisely decreased somewhat) because the stations' size grew with the market. There are presently about 3000 electric power stations in the world, of a certain size and connected to grids, and presumably a smaller number will be present in the year 2020. Consequently the number of plants to be constructed every year if we assume a life of 30 years will be 3000:30 or 100 per year at regime, which is not an extraordinary figure if we think it spread over the world. If we choose an energy vector different from electricity to carry around the energy, the number of reactors will depend on the cost of transportation. If we take hydrogen as an example, transportation costs in the proper context are an order of magnitude lower, and this makes generation possible in fewer and larger machines — say 100 for the whole world, with a replacement ratio of 3 per year. Does this still sound too many?

I am not entering into the complex question of financing energy systems development. I am just attracting attention to the fact that final consumers now pay for their energy something in the range of \$1.5 × 10¹²/year.

Yours faithfully,

C. MARCHETTI

International Institute for Applied Systems
Analysis, Laxenburg, Austria

Fast reactor safety and the fire at Beloyarsk

SIR, — Vera Rich's piece (31 January, page 420) based on a clandestine report of a fire at Beloyarsk in the USSR associates the fire with the fast reactor (BN600), at that site, and implies faults in the safety arrangements for that and, by implication, other fast reactors.

Beloyarsk is the site of two graphite moderated steam-cooled reactors, which were completed some years ago, and of the fast reactor BN600 which, at the time of the alleged fire, was still at least 12 months short of completion. The assumption that the fire, if any, might have led to the escape of radioactive sodium from the primary circuit of this reactor is, therefore, questionable, to say the least.

BN600 is a pool type reactor in which the core, pumps and primary heat exchangers are submerged in sodium contained in a strong double-skinned reactor tank. There is, therefore, no circuit, in the physical sense, which could “rupture” and “cause an explosion scattering radioactive material in a cloud . . .”. Vera Rich's reference to “the 1957 Kyshtym disaster” is equally inappropriate in the light of our ignorance of the nature, cause, or extent, of this incident.

It is not clear what implication the reader is meant to draw from the remark that “the fire at the Shevchenko fast breeder . . .” was not technically a “nuclear disaster”. This topic has previously been ventilated in your columns and information has been supplied which demonstrates both that this fire was no sort of disaster and that no radioactivity was involved since the circuit which leaked was a secondary sodium circuit external to the reactor.

Fast reactor safety is of public importance and, in your columns at least, deserves a more objective treatment than is displayed in Vera Rich's article.

Yours faithfully,

R.D. SMITH

NEWS AND VIEWS

The emergence of modern man

from Gail Kennedy

THE emergence of our own species remains one of the most elusive problems in palaeo-anthropology. Our increasing knowledge about very early hominids, such as the australopithecines, only serves to emphasise our lack of understanding of our own more immediate origins. In recent years, however, a few specimens have been found which give us tantalising views of the emergence of *Homo sapiens* from *Homo erectus*, the presumably ancestral species. One such discovery is reported in this issue (page 55). This well-preserved skull, Laetolil Hominid 18, was recovered in 1976 from the Ngaloba Beds at Laetoli, Tanzania. These beds are in the same area and stratigraphically overlie the Laetolil Beds in which Mary Leakey has found the fossil remains and footprints of early australopithecines.

L.H. 18, dating to about 120,000 years ago, shows a combination of advanced and primitive features. The overall expansion of the skull seen in the vertical parietals, rounded occiput and cranial capacity (1200 cm³) places it nearer modern sapients than to earlier *H. erectus*. In contrast to these more modern features, the large brow ridges, low, sloping frontal, marked bone thickness and certain features of the cranial base place L.H. 18 nearer to the ancestral group. Similar combinations of primitive and advanced characters are seen in other 'archaic' sapients from eastern and southern Africa such as the Omo skulls from the Kibish Beds in Ethiopia and the Broken Hill (Kabwe) skull from Zambia. The dates for these specimens are not entirely satisfactory but the Omo skulls may date to about 130,000 years ago (Butzer *et al.* *Quaternaria* 11, 15; 1969) and Broken Hill to about 110,000 years ago (Bada *et al.* *Proc. natn. Acad. Sci. U.S.A.* 71, 914; 1974). Even less securely dated but

also somewhat morphologically intermediate between *H. erectus* and *H. sapiens* are skulls from Saldanha in South Africa, Bodo in Ethiopia and Ndutu in Tanzania. As a group, these skulls are very heterogeneous but it is undeniable that they demonstrate varying degrees of sapientisation of the underlying *H. erectus* template. Skulls like Bodo and Ndutu, for example, occupy the more primitive *H. erectus* end of the morphological spectrum while others, such as L.H. 18 and Omo differ in fewer ways from modern *Homo sapiens*. Combined primitive and advanced characters are also seen in certain elements of the post-cranial skeleton such as the femora from the Broken Hill locality and from the Guomde Formation east of Lake Turkana (KNM-ER 999) (Kennedy, in preparation). This latter specimen may date to about 100,000 years ago (Fitch *et al.* *Nature* 252, 213; 1974).

The recognition that populations demonstrating a combination of *H. erectus* and *H. sapiens* features existed in Africa before 100,000 years ago poses some very intriguing questions. One such question concerns the source and nature of the evolutionary stimuli which led to the emergence of the modern species. Throughout its long evolutionary history, *H. erectus* demonstrated very little, if any, evidence of progressive morphological change. The earliest presently recognised members of the species, from the Lake Turkana area of Kenya and from Java, predate 1.5 million years. From this time through the Middle Pleistocene there is no clear evidence of progressive morphological advancement. According to some workers the first evidence of sapientisation occurred 300,000 to 400,000 years ago, during European Second Interglacial times. Others however, would maintain that the transition did not occur until about 100,000 years ago, during the Third Interglacial period. The group of archaic

hominids under discussion here, including L.H. 18, Omo and Broken Hill, may add slightly greater weight to a later transitional phase.

In any case, the long period of morphological stasis in *H. erectus* was ended by the appearance of individuals with significantly expanded, less angular skulls and thinner bone structure. It is of great interest that these more advanced morphological characters are not accompanied by obvious advances in stone tool technology, subsistence efficiency, settlement size or duration of occupation. This suite of traits is conventionally thought not to occur until the Upper Palaeolithic, around 35,000 years ago. Moreover, geographic range, already broad in *H. erectus* does not appear to change in the initial phases of sapientisation. What factors then were responsible for the evolutionary pressures and responses which ultimately led to the replacement of *H. erectus* by *H. sapiens*? Although the answer, in a very general way, may rest on increasing complexity of the behavioural repertoire and social organisation a more precise delineation of the process has not yet been accomplished.

A second question concerns the relationship of the very distinctive Neandertals both to these archaic sapients and to modern man. Controversies have continued for many years over whether anatomically modern man rapidly emerged from a single Neandertal/early sapient lineage in the Fourth Glacial or whether Neandertal and sapient lines diverged separately from a common ancestor sometime in the Middle Pleistocene. This hypothesis would view the two lines in coexistence until the extinction or assimilation of the Neandertals between 20,000 and 30,000 years ago. The Neandertal complex of characters first becomes visible in the fossil record in Europe during the Third Interglacial and is

G.E. Kennedy is in the Department of Anthropology, University of California, Los Angeles.

found widely distributed in Europe and southwest Asia during the early part of the Fourth Glacial. If the dates for the archaic sapients, such as L.H. 18, Omo and Broken Hill are accurate then this group preceeds the first known appearance of the Neandertals by a very short period of time. However, the highly distinctive suite of features which characterises the Neandertals is not present in the preserved remains of the archaic sapient group. Absent in the latter group are such Neandertal features as the occipital 'chignon', rounder (as opposed to vertical) parietals, very large cranial capacity and curved, robust long bones. Thus, whatever

the nature and origin of the Neandertal complex of characters, much of this morphology is not reflected in the archaic sapients which immediately pre-date them. From this evidence, can it be argued that a single lineage, anatomically progressive 110,000 to 130,000 years ago, rapidly evolved into the Neandertal populations (which are primitive in many features), then just as rapidly, later evolved into anatomically modern man? On the basis of the available evidence now emerging in Africa a dual lineage, extending back more than 100,000 years, seems a more likely hypothesis. Further confirmation from the fossil record, however, is required. □

considerably greater than the greatest alternating (peak) field applied. This seems to mean that the act of rotation, or 'tumbling', may considerably enhance the effect of a given peak alternating field, in demagnetising a given coercivity range within a sample. Effectively it makes the tumbling method a more powerful demagnetisation method than the stationary one.

Meanwhile, in this issue of *Nature* (page 48) A. Stephenson, of the University of Newcastle-upon-Tyne, reports his direct observations of the torque developed in a specimen which is rotating about an axis at right angles to an alternating field axis. The torque is quite appreciable, and is clearly related to the acquisition of rotational remanent magnetisation. Stephenson uses these results in support of a theory which relates rotational remanent magnetisation right back to the Barnett gyromagnetic effect; where a rock, rotating in the absence of a magnetic field, acquires a magnetisation caused by the alignment of internal magnetic moments along the axis of rotation (*Rev. Mod. Phys.* 7, 129; 1935).

It may well be that rotational remanent magnetisation is providing us with a means to investigate the Barnett effect, which has hitherto been very weak and difficult to deal with. According to Stephenson, the reason it has such a large effect in these experiments is that we are dealing not with the rate of rotation of the whole rock sample, but with the rate of rotation of the magnetic moment of a single magnetic grain when it is flipping between stable states. Since flip times are very brief, such rotational rates can be equivalent to 3×10^7 rotations per second greater. One could never hope to rotate any bulk material in the laboratory at such a speed, to enhance the Barnett effect.

However, that is not the end of the story. A second paper in this issue (page 49), again by Alan Stephenson, shows that curiously enough one does not even need the rotation of the specimen to produce what Stephenson terms a 'gyromagnetic remanent magnetisation'. He shows that one can achieve a similar magnetisation whenever one sense of flip predominates during alternating field demagnetisation, and that this will be observable whenever the magnetic material is sufficiently anisotropic. He has, with considerable ingenuity, manufactured an anisotropic specimen from stacked strips of magnetic recording tape. Sure enough, he is able, with no specimen rotation during an alternating field 'demagnetisation', to induce a remanence into the specimen which is clearly related to its anisotropy and which confirms his suggestion that gyromagnetism is the basis of the whole effect.

Stephenson's and Edwards' experiments are dealing with an effect which will touch upon several kinds of research. First, rotational remanent magnetisation provides us with a fairly easy means of studying gyromagnetism itself. At least

Gyromagnetisation: rocks in a spin

from R.L. Wilson

THE fascinating phenomenon of rotational remanent magnetisation (RRM) was unexpectedly discovered some 15 years ago as a result of geophysicists' attempts to interpret the natural permanent magnetisation of their rock samples. In the process of trying to separate the various magnetisations acquired by the rock during its lifetime by demagnetising the rock in an alternating magnetic field, it was found that slow rotation of a sample during alternating field demagnetisation could induce a remanence in the sample along the rotation axis even when no steady (for example geomagnetic) field was present. This phenomenon remains largely unexplained but several attempts at partial explanation are now emerging spurred on by novel and ingeniously derived experimental results.

The serendipitous discovery of RRM followed the use of a method of alternating field demagnetisation devised by Brynjolfsson and Sigurgeirsson at the University of Iceland (*Adv. in Phys.* 6, 247; 1957) to overcome a problem found in early attempts to demagnetise rocks by the application of decreasing alternating fields. It had been found that far from totally demagnetising the rock one actually replaced the original magnetisation with a new one due to the combination of the alternating field and the geomagnetic steady field in the laboratory.

One way of avoiding this was to cancel the local geomagnetic field in some way (As & Zijdeveld *Geophys. J.* 1, 308; 1958) but another was to 'tumble' the specimen to randomise the magnetisation due to the combined alternating and steady (geomagnetic) fields. Brynjolfsson and Sigurgeirsson developed a very clever method which involved rotating the sample

about a single axis defined by its direction of natural magnetisation and applying the demagnetising fields perpendicular to the rotation axis of the sample. As the two magnetisation components had different properties, the total natural magnetisation vector sometimes rotated through quite large angles during demagnetisation, and so the sample was at each stage reoriented in the apparatus to maintain the new direction of natural remanence aligned with the axis of sample rotation.

When we duplicated this apparatus in Liverpool, deciding (for some reason which no-one can now remember) that every other demagnetisation process would take place with the sample turned upside-down with respect to the rotation axis, we obtained to our astonishment field demagnetisation curves which clearly zigzagged about the usual smooth demagnetisation curve. The specimens were demagnetised less when oriented one way up than the other. The first observations of this effect had been published in 1967 by Doell and Cox (*Developments in Solid Earth Geophysics* 3; *Methods in Palaeomagnetism*, Elsevier, 1967) but they had used three-axis tumblers and their results were much more complicated and were not pursued. Eventually the idea of RRM was arrived at (Wilson & Lomax *Geophys. J.* 30, 295; 1972).

Once this phenomenon had been accepted the problem was to explain it and some recent experimental results are throwing light on this problem.

Interesting experiments by J. Edwards at Aberdeen University (*Geophys. J.* in the press) show that one can induce larger rotational remanent magnetisations by rotating the sample during only part of the demagnetisation process. He also shows that the slow rotation affects magnetic grains whose coercive forces are

Rod Wilson is Professor of Geophysics at Liverpool University.

experimentally there is little difficulty in reproducing the effect, but the theoretical interpretation of the results may be fairly difficult. Second, gyroremanent magnetisation may help us to measure and study magnetic anisotropy from the point of view of the solid state physicist. Third, the measurement of magnetic anisotropy in rock samples may be carried out by this new method, and used to interpret the stress histories of rock samples during geological time; the long term stress undergone by rocks often causes recrystallisation, the crystals (including the magnetic crystals) becoming aligned in a manner which is related to the stress field present during recrystallisation. Fourth, the under-

standing of rotational remanent magnetisation may help palaeomagnetists to learn how to demagnetise their samples in a more effective way than hitherto. Stephenson's second paper shows that even a stationary specimen in zero steady field, if anisotropic, will acquire an induced remanence during 'demagnetisation'. The practical demagnetisation problem then becomes "How does one tumble a specimen optimally to avoid induced rotational remanence in isotropic samples, gyroremanence in anisotropic samples, and ordinary anhysteretic remanence due to imperfect cancellation of the geomagnetic field?". A problem of some complexity, although it could just have a simple answer.

ILPAT 1.2 is present in all the clones (as expected) but it is flanked by different DNA sequences in each case, implying genetic rearrangement. Moreover, the arrangement is different in all the clones studied not just in the clone expressing ILPAT 1.2.

In this respect the results differ from those of Hoeijmakers *et al.* (this issue, page 78). These workers have prepared cDNA clones from four variants of *T. brucei* in a very similar fashion. The genes corresponding to these variant-specific cDNA clones were then analysed in DNA digests from all four strains by the same Southern blot technique and again the results are consistent with genomic rearrangements. The important and unexplained difference between this and the previous work is that the rearrangement is found only in the homologous variant, that is, the one expressing the variant antigen corresponding to the cDNA probe.

In many ways this fits much better with existing ideas and models for such genetic rearrangements. Hoeijmakers *et al.* interpret their results to show that the same basic gene copy is present in all variants examined, but that the homologous variant seems to show an additional copy of the gene flanked by different DNA sequences and which must presumably be linked with expression of the antigen. The appearance of such an expression-linked copy could be explained by insertion of a transposable promoter next to one of the two copies of the gene which would be found in a diploid organism. Unfortunately information on the ploidy of the trypanosomes is still lacking. A second attractive possible mechanism is gene cassetteing, analogous to the interconversion of yeast mating types. The mating type locus of *S. cerevisiae* can exist in two interconvertible states, a or α , which control the ability of yeast cells to mate and sporulate. The a and α genes are distinct co-dominant entities, which can be regarded as non-homologous blocks of regulatory information. On the basis of genetic evidence it was thought that yeast cells contain a silent (unexpressed) copy of both the a and α information, and that the mating type is controlled by insertion of a copy (or cassette) of one or other of the genes into the mating type locus. Evidence compatible with such a model was presented in *Nature* recently (Hicks, Strathern & Klar *Nature* 282, 478; 1979; see *News & Views* 283, 811; 1980) and such a cassette hypothesis could also explain the data presented by Hoeijmakers *et al.* for the variant antigen genes.

If translocation, by whatever mechanism, is involved in antigenic variation, how can the non-random generation of variants be explained? Here the accumulating data on RNA sequences around splicing junctions may provide a clue. Lerner *et al.* (*Nature* 283, 220; 1980) have tabulated hnRNA sequences at 43 intron/exon splice junctions and although

How trypanosomes change coats

from Mervyn Turner

THE concept of the 'mobile' gene is fast becoming part of the dogma of molecular biology. Precise somatic genetic rearrangements are now being recognised at the basis of the expression of a growing number of genes. From being considered a genetic freak when they were discovered many years ago, translocatable elements in maize have now been joined by immunoglobulin genes and yeast mating type genes in eukaryotes and by the bacterial insertion elements and transposons. The newest additions to the list of mobile genes in eukaryotes are the genes specifying the wide repertoire of surface antigens in trypanosomes. It is now clear that the antigenic variation seen in these parasites of man and his domestic animals is a result of genetic rearrangement (Williams *et al.* *Nature* 282, 847; 1979; Hoeijmakers *et al.*, this issue of *Nature*, page 78).

Trypanosomiasis affects both man and domestic animals with profound economic consequences across a wide belt of Africa. The salivary trypanosomes are parasitic protozoa normally transmitted cyclically by tsetse flies. The trypanosome survives in the bloodstream of the mammalian host by periodically altering its antigenic profile so that the developing immune response of the host is abortive. The disease is therefore characterised by a relapsing parasitemia with each recrudescence representing the development of immunologically distinct variants. Clones of trypanosomes grown from a single organism can undergo variation, and the same antigens can often be detected in the bloodstream before and after the cyclical transmission, implying that a single organism contains all the necessary information to produce variants, and that variants do not arise by mutation. Although there seems to be no strict

sequence in which the different variants appear, there does seem to be a definable order of priority. The total number of variants which can be expressed by a single clone of trypanosomes is not known but it seems likely to run into hundreds. The variant antigens are glycoproteins of molecular weight about 60,000, which cover the entire surface of the trypanosome. Purified antigens show marked differences in isoelectric point and amino acid composition and the only reported protein sequence data show no homologies within the N-terminal 30 or so residues in four antigens isolated sequentially during the same rabbit infection.

The mechanism by which the information encoding these antigens is stored and expressed is obviously of interest, and two groups have now reported experiments bearing on this point. Williams, Young and Majiwa (*Nature* 282, 847; 1979) partially purified variant-specific mRNA from a clone of *Trypanosoma brucei*, in this case ILPAT 1.2, prepared double-stranded cDNA and inserted this into the plasmid vector pBR322. A DNA clone containing a 902 base pair coding sequence of variant-specific DNA corresponding to about half the antigen, was identified by hybrid-arrested translation. A probe prepared by nick translation of this sequence was then filter-hybridised to a Southern blot of restriction endonuclease fragments of nuclear DNA from four different clones of *T. brucei* including ILPAT 1.2. Three of these were interrelated, in that they were derived from different relapses within the same strain. The fourth was obtained from an unrelated strain.

In each case the probe hybridised strongly to one or more bands of nuclear DNA, the size of the hybridising fragments differing in each clone of *T. brucei*. The clear implication is that the gene encoding

Mervyn Turner is at the MRC Biochemical Parasitology Unit, Moltano Institute, Cambridge.

the sequences differ it is possible to deduce an idealised 'consensus sequence' using the most commonly found arrangements of bases. By analogy, translocation-specific DNA sequences may exist within the *T. brucei* variant antigen gene repertoire, one such sequence being associated with each gene. The degree of homology with the

ideal 'consensus sequence' could then determine the frequency with which translocation occurred at that particular variant. Clearly sequences from genomic DNA clones will be of immense value in any further studies on the mechanism by which this protozoan Generator of Diversity operates. □

More sensitive immunoassays

from Roger Ekins

A NEW immunological assay method, claimed to be considerably more sensitive than radioimmunoassay, has recently been reported. C. Harris and coworkers have developed an 'ultrasensitive enzymatic immunoassay' (USERIA) applied in this instance to detect cholera toxin and rotavirus (*Proc. natn. Acad. Sci. U.S.A.* **76**, 5336; 1979). Radioimmunoassay (RIA) and related methods have played a vital part in endocrinology, and subsequently in other areas of biomedical science since their original development some 20 years ago. Fundamental to these techniques was their exploitation both of the structural specificity characterising antibodies and other specific binding proteins and of the sensitivity of 'signal detection' implicit in the use of radioisotopic labels. These attributes, in combination, provided the basis of assay methods of sufficient sensitivity and specificity to identify and measure the often minute concentrations of many biologically active substances present in biological fluids.

These techniques introduced a new principle into microanalytical methodology: that is, the estimation of the amount or concentration of a substance of interest (the 'analyte') by observation of its distribution between 'reacted' and 'unreacted' moieties following its interaction with a strictly limited amount of the specific reagent (antibody, for example) used. This principle differs from that underlying most traditional analytical methods in biochemistry, in which the estimate of the concentration of an analyte relies on observation of the effect on (or

distribution of) a theoretically unlimited amount of a specific reagent following its interaction with the substance of interest for example, the measurement of a substance by exposure to light and observation of the extent of light conversion to fluorescent radiation. This principle underlies the immunoradiometric (IRMA) — 'radiolabelled antibody' — assay techniques developed a few years later in which excess of the specific reagent (radiolabelled antibody) is allowed to react with the analyte.

IRMA methods — like conventional RIA techniques — rely on a combination of the specificity of molecular recognition characteristic of antibodies (and other specific binding proteins) with the sensitivity inherent in radioisotopic measurement techniques. Nevertheless, although both IRMA and RIA methodologies possess many technical features in common, the contrasting analytical principles which they represent imply that they differ fundamentally both in their sensitivity and specificity characteristics, and in the overall incubation times required to carry out an individual measurement (Ekins in *Radioimmunoassay and Related Procedures in Medicine* **1**, 281, IAEA, Vienna, 1978). These distinctions arise largely as a result of the differing influence of the Law of Mass Action on the physicochemical reactions between analyte and specific reagent which constitute the basis of both analytical approaches. In particular, the 'labelled reagent' methods (such as IRMA) offer potential sensitivities many orders of magnitude higher than equivalent 'labelled analyte' assay techniques (such as RIA), primarily because the sensitivity of methods using the latter approach is

essentially limited by the avidity of the specific reagent which reacts with the analyte, as revealed by the equilibrium constant of the reaction. This theoretical constraint does not apply to the sensitivity of 'labelled reagent' methods whose ultimate sensitivity limits are primarily imposed by classical considerations of signal-to-noise ratio, and implicitly by the 'specific activity' (observable events/unit time/unit mass) of the label used.

It is particularly in the context of 'labelled reagent' methodologies that labels other than radioisotopes are likely to offer significantly greater sensitivity and precision, together with absence of bias and shorter assay times. They may also circumvent the problems and hazards of handling radioisotopes which have frequently, though not always legitimately, been advanced as a reason for the ultimate abandonment of the current generation of radioassay methods.

Enzyme-linked immunosorbent assay (ELISA) methods — conceptually identical to IRMA techniques and differing only in their substitution of an enzyme for a radioisotopic label — provide an example of a non-isotopic labelled reagent method which has proved valuable, for example, in agriculture (for the identification of plant viruses) in tropical medicine, and in other biomedical contexts, particularly those in which sophisticated instrumentation is out of place. Nevertheless, conventional ELISA methods have generally — though not invariably — failed to attain the high sensitivities which are implicit in the labelled reagent approach, essentially because the 'noise' (consequent upon 'non-specific' labelled antibody binding) is sufficiently large in relation to the 'signal' (generated by the specifically-bound antibody/enzyme-label complex) to preclude the detection of very low levels of individual analytes.

So the recent description, by Harris and coworkers (*Proc. natn. Acad. Sci. U.S.A. op. cit.*) of their ultrasensitive enzymatic radioimmunoassay is of considerable interest. Aside from the further terminological confusion inflicted on an already chaotic area of nomenclature, their methodological refinement is notable insofar as it utilises a radioactive substrate (^3H -AMP) for the quantitation of the specifically-

100 years ago

Artificial Diamonds

An unusually large audience gathered at the Royal Society last Thursday to hear Mr. Hannay's account of his artificial diamonds.

The President, after inviting discussion of the paper by Messrs Hannay and Hogarth, observed that probably the large audience

had assembled more especially in consequence of the general interest attaching to the next paper on the artificial formation of the diamond, and he felt that the valuable investigation just detailed showed Mr Hannay to be a person worthy of attention when he claimed to have made even so startling a discovery as that on the face of this next communication. With regard to this the President observed that the attitude of science was always sceptical, and the Society would need ample proof that the metamorphosis of carbon into diamond had been really effected. . .

The President having called for any observations on the notice by Mr Hannay, Mr Maskelyne said that the present differed from the numerous announcements and

other communications that have been heretofore made to scientific societies at various times purporting to record the artificial production of the diamond in this, that here the product so claimed to have been manufactured is really diamond. He had himself proved this by the simple tests of the mineralogist. He had deeply abraded topaz and sapphire with a particle of the substance and abraded them with the greatest ease; the angle of the cleavages of a crystalline fragment sent him by Mr Hannay was the angle between faces of the regular octahedron, and he had burnt a small grain of the substance on a platinum foil with the characteristic glow of the diamond, and without its leaving a residue.

From *Nature* **21**, 4 March, 421; 1880.

bound enzyme-labelled antibody used in a conventional ELISA method. By this manoeuvre, Harris and his colleagues have succeeded in increasing the signal-to-noise ratio they observe compared with that attained using colorimetrically-based ELISA methods, and have thereby extended the detection limits of this technique to 10^{-16} g (that is 6×10^2 molecules) in the case of cholera toxin. In so doing, they have confirmed the proposition that labelled reagent techniques in general, and labelled antibody methods in particular, are potentially capable of attaining sensitivities many orders of magnitude higher than the 'labelled analyte' or 'saturation assay' methods exemplified by conventional RIA. Aside from the explicit advantages in terms of the reduction in detection limits that this advance offers, a corollary of the far greater sensitivity inherent in 'labelled reagent' methods is the significantly shorter assay incubation times that are required to achieve acceptably precise results.

The technique described by Harris and his colleagues — which might more accurately be described as 'enzyme-amplified' immunoradiometric assay — nevertheless constitutes a somewhat unwieldy approach to the attainment of high signal-to-noise ratios. Nor does it meet the environmental objections to the use of radioisotopes that are increasingly being levelled against both RIA and IRMA techniques. However other forms of label now being developed may offer the same high sensitivities while minimising the complexity of the chemical procedures or of the physical instrumentation required. Two approaches potentially capable of yielding assay sensitivities of the same order as that provided by USERIA rely on the use of chemiluminescent labels as described by Simpson and his colleagues (*Nature* 279, 646; 1979), and of fluorescent markers — particularly those such as the chelated rare earth fluorophores which, as discussed by Soini and Hammilä (*Clin. Chem.* 25/3, 353; 1979) can be readily distinguished from background fluorescence by time resolution techniques. Such alternative labelling methods are under active exploration in several centres. Combined with the exploitation of the *in vitro* hybridoma techniques of antibody production pioneered by Milstein and his colleagues at Cambridge (Milstein & Köhler in *Antibodies in human diagnosis and therapy*, 271, Raven Press, New York, 1977) with which large quantities of monospecific antibodies can be produced, the emergence of simple and reliable assay procedures far surpassing current RIA techniques in sensitivity, precision, speed, specificity, convenience and overall reliability is within sight. The implications of such a prospect in relation to biomedical research, to routine clinical diagnosis, and to related fields such as agriculture, are not difficult to visualise. □

Methane from ridges

from Peter J. Smith

ONE of the more important, but underpublicised, elements of progress in the Earth sciences during the past decade has been the growing appreciation of the crucial role played by hydrothermal fluids in the vicinity of oceanic ridges. Interest in the subject has widened recently, largely because of the physical implications; there can be little doubt, for example, that hydrothermal circulation can go far towards explaining the curious heat flow variations observed across active ridges. Some of the most fundamental consequences of such circulation, on the other hand, are bound to be chemical, for there are few better ways of inducing significant chemical reactions in rocks than to have them bathed in hot chemically-rich fluids.

It is the chemical side which has now attracted Welhan and Craig (*Geophys. Res. Lett.* 6, 829; 1979) — that is to say, the 'chemically-rich' aspect rather than the way the fluids react with the lithosphere. The particular observational site is the crest of the East Pacific rise at 21°N , where recently discovered hydrothermal vents are discharging turbid waters (some black, some white) at temperatures of up to 400°C . Three samples of these waters were found to be enriched (compared with the ambient seawater) in helium and radon, as are most known hydrothermal fluids whether they come from the Red Sea, the

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

Guaymas Basin (Gulf of California) or other sections of the East Pacific rise. But Welhan and Craig find that the 21°N fluids are also highly enriched in hydrogen and methane — and that seems to be an original observation.

As the samples available to Welhan and Craig were contaminated by 'normal' seawater, numerical estimates are likely to be imperfect. Nevertheless, emission from the world oceanic ridge system, estimated by extrapolation from the East Pacific rise data, amounts to $1.3 \times 10^9 \text{ m}^3$ of hydrogen and $1.6 \times 10^8 \text{ m}^3$ of methane a year. These are, of course, unexpectedly large figures. The mean concentration of deep-ocean methane, for example, is only about $5 \times 10^{-6} \text{ ml kg}^{-1}$, which means that it can all be replaced by new methane from the ridges within a mere 33 years.

Where does the ridge methane come from? Is it, as is the helium, a mantle constituent brought to the crust in the magma rising at oceanic ridges, or is it produced in a reaction between the risen magma and the surrounding seawater? For the time being such questions remain unanswered. In raising them, however, it is curious that Welhan and Craig do not even mention Gold's recent hypothesis to the effect that the outgassing of methane present in the original Earth is still continuing (*J. Petrol. Geol.*, 1, 3; 1979, but given considerable publicity during 1978). Whatever one might think of Gold's hypothesis on the purely intuitive level, it is important that it should be measured against whatever data can be obtained.

Gondwanaland revisited

from Don Tarling

THE Fifth Gondwana Symposium* marked the coming of age of Gondwanaland 16 years after the inception of these symposia. There is now a clear consensus about the final configuration of this supercontinent some 180 million years ago. The unity of South America and Africa as 'western' Gondwanaland and of India, Australia and Antarctica as 'eastern' Gondwanaland has been widely accepted, but the fit of these two pieces has been controversial. New oceanic magnetic anomaly data now provide the required constraints (M.J. de Wit, Witwatersrand; M.W. McElhinny, Canberra; B.J.J. Embleton, CSIRO, Sydney; I. Dalziel, Santa Barbara).

The reconstruction was developed at a workshop in Johannesburg in July 1979 and is broadly similar to that of A.G. Smith & A. Hallam (*Nature* 225, 138; 1970) but

differs in several important respects. 'Eastern' Gondwanaland has been moved much further away from southeastern Africa, leaving room for the Mozambique Ridge, the Agulhas and Falkland Plateaux and so on. Malagasy, although still northerly, is also further from the East African coastline, although possibly not far enough to satisfy me.

The new reconstruction, as do all its predecessors, creates major difficulties in western Antarctica. It is clear that the Antarctic Peninsular existed in the Triassic-Jurassic so it can neither overlap the Falkland Plateau nor run parallel to southern South America (Dalziel). The 'solution' is, for the time being, to break up western Antarctica into discrete blocks that rotated during the Mesozoic evolution of this region. The structural grain of the Ellesworth Mountains is anomalous compared with the rest of Antarctica, but the evidence for its anticlockwise rotation is still largely based on the geometric requirements of the reconstruction itself. However, some palaeomagnetic evidence (K.S. Kellogg, US Geological Survey, Denver) now seems to be consistent with this interpretation. It is intended to use this fit as the base for a geological, geochrono-

*Held in Wellington, New Zealand on 11-16 February, 1980. The Proceedings will be published by Balkema Press at the end of 1980.

logical and resource geology map to be published at 1:10,000,000 in 1981 and de Wit requested data to assist in this. Such a compilation will allow further testing of the reconstruction but it is unlikely that location of the major blocks will be in error by more than a few 100 km. The importance of this map is thus to highlight areas for future research.

A major consideration was the extent of Gondwanaland. Nepal (C.J. Klootwyk, Canberra), Iran (H. Wensink, Utrecht) and Thailand (S. Bunopas & P. Vella, Wellington) were formerly parts of Gondwanaland and there is evidence that much of China (J.B. Waterhouse, Queensland; P. Tasch, Wichita) and possibly some central Asian blocks, with parts of southern Europe (D.H. Tarling, Newcastle upon Tyne), also formed parts of this supercontinent at various times, the degree of floral and faunal interchange between the Gondwanan and Laurasian continents having clearly altered as both continents evolved. The distribution of dinosaurs seems to indicate that Afro-

Indian links persisted well into Late Cretaceous times (E.H. Colbert, Flagstaff) although it is not clear if such links were provided by the Laccadive-Mascarene Ridge or whether access was along the Iranian-Afghanistan coastlines. Palaeobiogeographic provinces formed a significant part of the meeting, with the key glossopterid flora now being divisible into six stratigraphic units that have, so far, been correlated between India and Australia (J.F. Rigby, Geological Survey, Queensland; S.C. Shah, Geological Survey, Calcutta). The presentation of major advances in palynological correlations were predictable, but nonetheless of critical value for the Carbo-Permian (E.M. Truswell, BMR, Canberra) and Permo-Triassic (J. Anderson, Witwatersrand). Although this work solves many problems it also raises others; it destroys the previous, elegantly simple concept of a Gondwanaland drifting through polar regions and hence being glaciated at successive periods in different areas. The age of these ice sheet deposits are almost entirely Sakmarian (Lower Permian) and require much more complex explanations (D.H. Tarling in *Climatic Change*, (Ed. Gribbin) Cambridge University Press, 1978). □

vibrations with zero momentum parallel to the surface, as in infrared studies.

The short range interactions are much weaker but their effects can be separated because they can transfer large amounts of momentum to the electron (Ho, Willis & Plummer *Phys. Rev. Lett.* **40**, 1463; 1978). Tuning the spectrometer to the non-specular electrons immediately separates these processes, but at the price of requiring much greater sensitivity. We immediately gain two advantages: the need for a dipole moment is removed; and vibrations with non-zero parallel momentum can be seen. There is a further less obvious gain in information. The matrix element for the scattering involves an incident-wave momentum k_i an exit wave momentum k_f and the displacement of the j th atom, C_j , caused by the vibration:

$$\sum_j \int \exp\{i(\mathbf{k}_i \cdot \mathbf{r} - \mathbf{k}_f \cdot \mathbf{r})\} C_j \cdot \nabla V_j(\mathbf{r} - \mathbf{R}_j) d^3r \quad (1)$$

where V_j is the potential of the j th atom, assumed localised near \mathbf{R}_j . If we were investigating the modes of a molecule, it would be useful to know how C_j varied within the molecule. Equation (1) shows that the contribution of each atom to the matrix element has a phase

$$\exp\{i(\mathbf{k}_i - \mathbf{k}_f) \cdot \mathbf{R}_j\}$$

therefore by measuring at different values of $\mathbf{k}_i - \mathbf{k}_f$ it will be possible to identify the individual components of the mode, provided only that we already know the mean positions \mathbf{R}_j of the atoms. That is, we know the phonon 'wavefunctions' as well as the energy levels.

There is an analogy with angle-resolved photoemission experiments in which the energy and momentum of an ejected photoelectron implies by conservation the energy and momentum of the original state of the electron before excitation. (Li, Tong & Mills *Phys. Rev.* in the press). Alternatively knowing both the original and final electron E and \mathbf{k} we can infer the q and ω of the photon. If we read phonon for photon we have the EELS experiment (whether it involves the loss or gain of a phonon). The analogy extends even further: equation (1) gives the matrix element for interaction with a phonon defining atomic displacements C_j . The analogous matrix element for photoemission is

$$\frac{1}{\omega_j} \int \exp\{i(\mathbf{k}_i \cdot \mathbf{r} - \mathbf{k}_f \cdot \mathbf{r})\} \mathbf{A}_j \cdot \nabla V_j(\mathbf{r} - \mathbf{R}_j) d^3r$$

where \mathbf{A}_j is the 'A vector' of the photon field at the j th atom. This close analogy should lead to rapid development of the associated theory of EELS which will be needed to realise the full potential information in the data □

Vibrations of atoms at surfaces

from John Pendry

THE vibrational properties of atoms and molecules adsorbed on surfaces are determined by the detailed interaction with the surface: whether a molecule dissociates, to what degree an atom is coordinated by surface atoms, whether new species are formed. Knowledge of the way atoms vibrate is an essential complement to our static picture of atomic arrangements. The traditional tool for studying vibrations is infrared absorption, which has yielded much information about vibrations but is limited by the need for the bond to have a strong polar element to be infrared active, and in the case of metal surfaces by the electromagnetic boundary condition which allows only a normal component of the electric field. Electron energy loss spectroscopy (EELS) offers an alternative means of studying vibrational frequencies which to some extent escapes from these restrictions (Ibach *Phys. Rev. Lett.* **24**, 1416; 1970).

Experiments make use of 1-10 eV electrons, which can be monochromated to a few meVs. This represents much worse resolution than infrared can provide and severely restricts the power of the technique. It is unlikely that electron

spectrometry can approach 1 meV resolution and so the technique is mainly concerned with studying strong bonds to relatively light atoms. Despite these considerable restrictions EELS is proving a useful technique which is continually developing both experimentally and theoretically.

There are two ways in which electrons interact with vibrating atoms: through long range and short range forces. If the vibration has an associated dipole moment, an electric field extends far from the surface and operates on an approaching or receding electron for a relatively long period. If a dipole moment is present, this is the dominant mode for inelastic scattering. (Evans & Mills *Phys. Rev.* **B7**, 853; 1973). Because the forces are long range the electron loses energy but remains undeviated in direction. A specular reflection at the surface turns the electron around into an analyser which separates the inelastic component. Until recently this has been the predominant mode of operation of EELS experiments. The requirement of a dipole moment imposes some of the restrictions of infrared spectroscopy and the lack of any substantial momentum transfer to the electron in the inelastic collision limits the information that can be obtained to

REVIEW ARTICLE

The role of hormone receptors and GTP-regulatory proteins in membrane transduction

Martin Rodbell

Laboratory of Nutrition and Endocrinology, National Institute of Arthritis, Metabolic and Digestive Diseases,
National Institutes of Health, Bethesda, Maryland 20205

Cell membrane receptors for hormones and neurotransmitters form oligomeric complexes with GTP-regulatory proteins and inhibit the latter from reacting with GTP. Hormones and neurotransmitters act by releasing the inhibitory constraints imposed by the receptors, thus allowing the GTP-regulatory proteins to interact with and control the activity of enzymes such as adenylate cyclase. This theory may apply generally to membrane signal transduction involving surface receptors.

ADENYLATE CYCLASE, the enzyme that produces cyclic AMP, is part of a complex regulatory system that mediates the actions of hormones and neurotransmitters on their target cells. Structured within the lipid framework of the cell membrane, the enzyme system is composed of at least three classes of components (Fig. 1). Located at the outer membrane surface is the receptor (R) component containing a specific site for binding of hormones and neurotransmitters. At the inner face of the membrane are the catalytic unit (C) and the nucleotide regulatory component (N). The latter contains site(s) for binding GTP and is responsible for mediating the effects of GTP and the various hormones on the activity of C¹. Two types of N units have been distinguished functionally. One mediates stimulation (termed N_s), the other inhibition (N_i) of the adenylate cyclase activity by GTP. As discussed below, each type seems to be linked to separate classes of receptors for hormones and neurotransmitters.

Here I present a theoretical framework for the role of hormone receptors and N units in regulating adenylate cyclase activity. In essence, the theory suggests that the N and R units normally exist separately from C as aggregates or oligomers of an RN complex. In this complex, R inhibits interaction of N with GTP. Hormone binding to R triggers release of the inhibitory constraints imposed on N with resultant enhanced reaction with GTP, followed by breakdown of the oligomers to a monomeric RN complex. The latter reacts with C to form the holoenzyme structure depicted in Fig. 1. Depending on the type of R and N unit attached to C, the holoenzyme exhibits either increased or decreased production of cyclic AMP. In developing this theory, I review evidence for the existence of N_s and N_i and their complexes with R and C, describe the properties of the various components, give recent evidence that RN oligomers exist and discuss the possibility that the theory may be generalised to include R and N units that regulate membrane transduction processes other than adenylate cyclase.

The role of N_s in activation of adenylate cyclase

Before the discovery that GTP is the essential activator of adenylate cyclase² and that hormones enhance the nucleotide's action³, it was thought that hormone receptors interacted directly with the catalytic unit and that fluoride ion, a non-physiological activator, affected the catalytic unit directly⁴. It is now clear that the actions of both hormones (through their

specific receptors) and fluoride ion are mediated through proteins that bind GTP. First identified^{5,6} with GTP-photoaffinity analogues as a heat-stable 42,000 molecular weight protein in detergent extracts of avian erythrocytes, the protein (N_s) has been shown to exist in a variety of cell membranes. Cholera toxin has been particularly valuable for identifying N_s. Long known to stimulate the production of cyclic AMP in animal cells⁷⁻⁹, the toxin potentiates the activating effects of GTP even in the absence of hormones and affects other characteristics of the enzyme that suggest that N_s is its primary site of action¹⁰⁻¹⁴. This was firmly established when it was found that the toxin, which contains in its A₁ subunit an ADP-ribosylating activity, preferentially labels the 42,000-MW protein in the presence of ³²P-NAD (refs 15-17). Cells deficient in N_s by functional criteria also lack the toxin-labelled protein; addition of detergent extracts of membranes containing N_s reconstitutes the ability of hormones, guanine nucleotides, fluoride ion and cholera toxin to stimulate cyclase activity in membranes from cells genetically deficient in N_s but otherwise containing hormone receptors and adenylate cyclase^{18,19}. Thus, judged from several standpoints, N_s is an essential component in the activation of adenylate cyclase. Although its structure remains unknown, N_s must have highly conserved recognition sites that allow it to activate C derived from a variety of cells and to 'couple' with the several types of receptors that mediate the stimulatory actions of hormones.

Table 1 lists a few of the properties of N_s and C when separate and combined (combinations with R are discussed below). C uses MnATP preferentially as substrate^{20,21}. Only when combined with N_s does C use the natural substrate, MgATP, as effectively as MnATP¹². Association of N_s with C is reversible and is driven by the binding of guanine nucleotides to N_s (refs 6, 22).

Properties and role of RN complexes

In classical theories of hormone action, the binding event leads the receptor to adopt a structure that is favourable for action. The relationship between hormone binding (K_D) and action (K_{act}) on adenylate cyclase systems is complicated by the fact that two ligands, hormone and GTP, are required for action². This complexity is exemplified by studies of the glucagon-sensitive cyclase system in liver membranes²³⁻²⁵. Direct binding studies with labelled glucagon revealed that GTP at concentrations required for activation of adenylate cyclase in the

presence of hormone, converted 90% of the receptors to a state with a higher K_D than K_{act} ; the remaining 10% displayed both the kinetic and thermodynamic properties commensurate with hormonal activation of the enzyme. A similar distribution of glucagon receptor states is seen in intact hepatocytes²⁶ which presumably contain sufficient GTP to interact with N_s at the internal face of the cell membrane. A plausible explanation for the effect of GTP on K_{act} and K_D is the following set of reactions (modified from ref. 27)

in which hormone binding and action are initiated at step (1) with resultant formation of an 'activated' state of $N(N^*)$. Reaction of the latter with GTP (step 2) leads to a complex ($H \cdot R \cdot N \cdot GTP$) which preferentially couples with C to form the activated holoenzyme. The negative heterotropic effects of GTP (decreased hormone binding) derive from a lower-affinity form of RN when occupied by GTP and not complexed with C (step 2). Thus, association of the macromolecular components (R, N, C) enhances the binding affinity of the small ligands (hormone and GTP). In this 'uncoupled' equilibrium model, the final concentration of the activated holoenzyme is a function of the relative concentrations of both the macromolecular components and the small ligands. In the overall equilibrium, all RN complexes have equal potential to form complexes with C but the amount of RNC formed is limited by the concentration of C. In the case of the liver system, the latter may be 10% of R and N.

Evidence from β -adrenergic receptor systems supports the above reaction scheme. For example, agonists but not antagonists promote the negative heterotropic effects of GTP on catecholamine binding²⁸⁻³². This is consistent with an ordered reaction in which hormones promote interaction of N in the RN complex with GTP. Evidence that the negative heterotropic effects derive from the RN complex stems from findings that cells lacking C but containing N_s and R display the negative heterotropic effects of GTP on hormone binding²⁰. Furthermore, RN complexes have been isolated following detergent extraction of membranes and separation from C (or NC); such complexes show the effects of GTP on hormone binding seen with intact membranes^{33,34}. Membranes from cells genetically deficient in N_s fail to show not only responses to hormones and guanine nucleotides, but also heterotropic effects of GTP on

Fig. 1 Schematic representation of the components and organisation of the adenylate cyclase holoenzyme responsible for regulation by hormones and GTP. The receptor (R) is visualised as spanning the plasma membrane and having different segments (indicated by the shaded and cross-hatched areas) which have functions for binding of hormone, attachment to membrane and linkage with the nucleotide regulatory unit (N) that binds GTP. The N unit forms a bridge between R and the catalytic component (C) at the internal face of the membrane.

hormone binding to receptors; addition of extracts containing N_s to such membranes restores the ability of GTP to affect hormone binding³². Further evidence that the N_s unit responsible for activation of cyclase by guanine nucleotides, fluoride and cholera toxin is the same as that linked to R can be deduced from findings that cholera toxin affects the actions of GTP on both hormone binding and cyclase activity¹³. Accordingly, there is no need to invoke different regulatory N units linked to R and C, as has been suggested to explain differing properties of guanine nucleotide effects on hormone binding and adenylate cyclase activity^{27,33-37}. The differences can be explained by heterogeneous forms of N associated with the other components (RN, NC, RNC) having different properties with respect to affinities and actions of guanine nucleotides (Table 1).

The evidence cited above for the existence of RN complexes is based on the effects of GTP on hormone binding. On theoretical grounds, reciprocal effects of hormones on guanine nucleotide binding should also be observed. Recent findings^{38,39} that hormones promote the exchange of bound and free guanine nucleotides at the N_s unit provide further evidence that the R and N units are structurally linked. The functional consequences of this linkage on adenylate cyclase regulation are further discussed below.

It is evident that R units not associated with N units are nonfunctional with respect to adenylate cyclase activation by hormones; free R units in membranes have a lower affinity for agonists than do RN units (when unreacted with GTP)²⁸. Perhaps, free R units are formed from dissociation of RN units and are *en route* to endocytotic removal^{40,41}.

Table 2 lists receptors reported to show negative heterotropic effects of GTP on hormone binding and which are presumed, therefore, to represent RN complexes. Note that they fall into three categories: those involved in stimulation of adenylate cyclase (RN_s), those known to mediate inhibition of the enzyme (RN_i), and those which either do not interact with adenylate cyclase or whose function is unknown (RN_x).

Role of RN_i in the inhibition of adenylate cyclase by neurotransmitter and GTP

In contrast to its adenylate cyclase-activating role, GTP can inhibit some adenylate cyclase systems. First observed⁴² and characterised⁴³⁻⁴⁶ in rat adipocyte membranes, recent studies⁴⁷⁻⁴⁹ indicate that this process differs from the components that mediate stimulation by several lipolytic hormones in the same membranes. For example, adenosine promotes inhibition of adipocyte adenylate cyclase by GTP through processes which differ from the GTP-stimulatory process in their differential susceptibility to effects of sulphhydryl agents, proteases, divalent cations, sodium ions and mercurials.

Table 1 Properties of adenylate cyclase components

Components	Properties	Selected refs
C	Preferential reaction with MnATP as substrate	20, 21
NC	MgATP or MnATP as substrate when activated by Gpp(NH)p*, cholera toxin and NAD in presence of GTP, and by fluoride ion	16, 23
R	Low affinity for hormone agonists; no heterotropic effects of GTP	19
RN or (RN) ^p	GTP reduces affinity of R for hormone agonists. Hormones form tight-binding complex	24, 31, 35
RNC	Same as NC but responds to hormones and Gpp(NH)p; binds GDP tightly in absence of hormones. Hormones stimulate exchange of GDP and GTP at N site	38

*Gpp(NH)p is a GTP analogue that is not hydrolysed to GDP by GTPases in membranes.

The close functional linkage between the adenosine receptor (R -site⁵⁰) and N_i in the adipocyte suggests that there is an RN_i complex for adenosine in fat cells. It appears that RN_i and RN_s complexes in the fat cell interact with a common C unit⁴⁹. Opposing regulation by independent types of RN complexes (Fig. 2) may be widespread, particularly in cells that have adenylate cyclase systems governed by the endocrine and neuroendocrine systems. Receptors for such neurotransmitters as opiates, dopamine, catecholamines (α -adrenergic) and cholinergic agents (muscarinic) also mediate inhibition of adenylate cyclase by a GTP-dependent process⁵¹⁻⁵⁴. In common with the adenosine receptor linked to N_i in adipocytes, these receptors are sensitive to sodium ions. Interestingly, in the few cases examined, negative heterotropic effects of GTP on agonist binding are observed with the same membranes showing the GTP dependency of agonist inhibition of adenylate cyclase; sodium effects on agonist binding are also observed (Table 2). These findings suggest, by analogy with the role of RN_s complexes in the stimulation of adenylate cyclase, that RN_i complexes are involved in the inhibitory process.

The structure of RN

The technique of target size analysis has recently been used to examine the size of adenylate cyclase systems in various conditions in their membrane-bound form (for application and theory see ref. 55). Results obtained from liver⁵⁶, adipocytes and turkey erythrocyte membranes are shown in Table 3. The minimal size unit expressing activity is that obtained with MnATP as substrate and no activating ligands; it is presumed to represent C . The size increases significantly as N_sC is produced with pre-activation by guanine nucleotides or fluoride ion. Activation by hormones and GTP which should produce the holoenzyme (RNC), is accompanied by a further increment in size commensurate with this premise. In the case of the liver system, the sizes of the regulatory complexes (RN_s) were estimated from studies of the binding of labelled glucagon in the presence of GTP and from the 'ground-state' cyclase activity, that is the size of components present before coupling. Both studies indicate that the RN_s structure in the liver has a MW in the range $6-13 \times 10^5$, which is three to six times the estimated size of the RN unit associated with the holoenzyme. The conclusion from these findings is that RN_s exists as oligomers when not linked to the C unit. Note in Table 3 that the unit (presumably RN_i) responsible for inhibition of adipocyte adenylate cyclase by adenosine and GTP is significantly larger than the oligomeric RN_s unit that mediates the stimulatory effects of hormones and GTP on the same enzyme system. Although target analysis

Fig. 2 Schematic representation of dual regulation of adenylate cyclase systems by stimulatory and inhibitory hormones and neurotransmitters. Depicted in the model are two classes of receptor (R) one (R_s) mediating hormone effects through stimulatory nucleotide regulatory units (N_s) and another (R_i) mediating inhibitory effects through linkage with an N_i unit that binds GTP and inhibits adenylate cyclase activity. The R_iN_i units require Na^+ for the effects of the various inhibitory agents on adenylate cyclase (C) activity.

cannot give the structure and composition of the target, it can be inferred from the size differences that the stimulatory and inhibitory processes reflect different structures that are multiples of the RN units comprising the holoenzyme.

Although the sizes of the adenylate cyclase system in turkey erythrocytes display increments with increasing regulatory complexity, this system does not show the oligomeric structures of RN_s ; the functional size remains identical before and after activation with catecholamines and guanine nucleotides. Possibly, R , N and C are already assembled in the holoenzyme structure due to prior activation of the enzyme system during isolation of the membranes. Pre-assembly may explain some notable differences in kinetic behaviour of the turkey and liver adenylate cyclase systems (discussed below). A pre-assembled unit is also consistent with the report⁵⁷ of a linear relationship (rather than the usual hyperbolic relationship) between hormonal activation and receptor occupation in the turkey system.

A model for hormone and GTP action on adenylate cyclase

The existence of oligomeric complexes of RN provides a structural basis for the uncoupled equilibrium reactions described above. For illustrative purposes, the model depicted in Fig. 3 shows a tetrameric structure of RN units existing in two

Table 2 Hormone receptors regulated by GTP (the RN complex)

Receptor type	Source	Type of N unit*	Comments	Selected refs
Glucagon	Rat liver	N_s	GTP = GDP; Gpp(NH)p and Gpp(CH) ₂ p less potent	24
Catecholamines (β -receptors)	Several cell types	N_s	Divalent cations promote binding of agonists; only agonist binding affected	28-32
Prostaglandin E	Thyroid, frog erythrocyte	N_s	Binding promoted by Ca^{2+} ions	98, 99
Dopamine	Corpus striatum	N_s, N_x	GTP = GDP > Gpp(NH)p; agonist specific	100, 101
Muscarinic	Canine and rat myocardium	N_i	Methacholine inhibits GTP effects on β -receptor; Na^+ probably affects binding	102, 103
	Neuroblastoma x glioma cells	N_i	Mg^{2+} enhances agonist binding	105
Catecholamines (α -receptors)	Brain	N_x	GTP = Gpp(NH)p > GDP; Na^+ affects agonist binding	106, 107
	Rat liver	N_x	Agonist specific	83
Angiotensin	Adrenal cortex	N_x	Agonist binding affected by Na^+ in same manner as by GTP	84
Opiates	Brain	N_x	Na^+ affects binding of agonists and antagonists. Two distinct opiate receptors	52, 104, 108

In all cases, addition of guanine nucleotides decreases binding of hormone or neurotransmitter to specific receptors in isolated membrane preparations.

* N_s is N unit linked to stimulation of adenylate cyclase; N_i affects inhibition of the enzyme; N_x is an N unit that is either not related to cyclase activity or has an undetermined relationship to a specific signal-processing system in the cell membrane.

configurations: an unoccupied structure (A) which favours binding of hormones but not GTP, and a hormone-induced or stabilised structure (B) which favours reaction of GTP with the N component (equivalent to N^* in the previous reaction scheme). Reaction with GTP results in dispersion of the oligomer to monomers (at this stage the negative heterotropic effects of GTP occur) which uniquely react with C to form the holoenzyme that converts MgATP to cyclic AMP. In broad terms, this 'disaggregation-coupling' model for hormone and GTP action can be likened to the manner by which cyclic AMP controls through its receptor the activity of protein kinase; the latter involves a change in the association of dimeric regulatory and catalytic subunits⁵⁸. In the case of hormone receptors associated with adenylate cyclase systems, their interaction with N units in the oligomeric state constrains the ability of N to react with GTP, thus preventing the formation of the 'active' form of the regulatory N unit (N_s or N_i). It follows that cyclase systems devoid of receptors linked to N should display high reactivity with GTP. This has been reported⁵⁹ recently with a strain of HeLa cells deficient in β -adrenergic receptors; when the same cells become enriched with receptors, catecholamines are required to restore the level of activity seen with GTP alone in receptor-deficient cells.

The disaggregation-coupling model has several other important features that serve to distinguish it from previous theories of hormone action⁶⁰⁻⁶². First, assuming that the oligomers of RN are unreactive with C, it provides a means for functional compartmentalisation of RN units from C and explains the observed dependency of the reaction on both hormone and GTP. Second, an oligomeric structure of RN allows for homotropic subunit interactions such that minimal occupation by hormones may cause near maximal production of the functional activating 'signal' (the RN-GTP monomer) in the presence of saturating concentrations of GTP; marked activation of adenylate cyclase with minimal occupation of receptors has been observed with several cyclase systems^{24,57,63,64}. Thus, although full occupation of receptor subunits may drive complete coupling of RN with C, coupling may occur even when these units are not occupied with hormone. Third, because the oligomeric RN structure is inert with respect to activation of adenylate cyclase, aggregation of uncoupled regulatory units is a means of 'turning off' the reaction cycle. How 'uncoupling-aggregation' is accomplished and what factors control this part of the cycle remain unknown. Possible candidates are cytosolic factors reported to affect adenylate cyclase activity⁶⁵⁻⁶⁹. Additionally, factors intrinsic to or associated with the plasma membrane may be essential in the aggregation-disaggregation cycle; these factors could include cytoskeletal elements⁷⁰ which may stabilise the aggregated units in the membrane; interestingly, agents that disrupt cytoskeletal structures have been reported^{71,72} to enhance cellular production of cyclic AMP in response to hormones.

Emphasis has been placed recently on regulation of hydrolysis of GTP by a GTPase putatively associated with the N_s unit^{14,73,74}

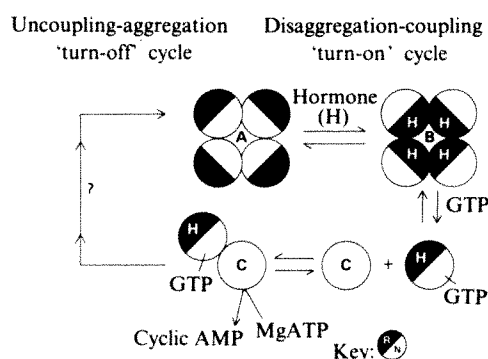

Fig. 3 A model for coupling of the receptor-nucleotide regulatory units (RN) to the catalytic unit (C) of adenylate cyclase and the role of hormone and GTP in this process. See text for detailed description.

Table 3 Functional sizes of adenylate cyclase components

Enzyme source	Components (MW $\times 10^5$)				
	RN_s	C	N_sC	RN_sC	R_iN_i
Rat liver: R = glucagon	6-13*	1.5	2.3	3.5	—
Fat cell (rat)					
R = catecholamine, ACTH	13	†	2.3	†	>13
R_i = adenosine					
Turkey erythrocyte	ND	0.9	1.8	2.5	—
R = catecholamine					

Sizes were determined by target size analysis using high energy irradiation. See ref. 56 for methods for determining size and rationale for assigning components to size. Data for fat cell and turkey erythrocyte data are unpublished. ND, Not detected.

* Estimated both from GTP-sensitive glucagon binding and adenylate cyclase activity of 'ground-state' enzyme.

† Not determined.

and the role of this regulation in turning-off the GTP-activation process. In turkey erythrocyte membranes, catecholamines and cholera toxin affect GTPase activity and GDP is a potent inhibitor that binds tightly to N_s (refs 38, 39). The differences in the kinetic characteristics of the liver cyclase system in its response to GTP and Gpp(NH)p are consistent with a GTPase being involved in its dynamic characteristics⁷⁵. However, GDP has been shown to stimulate liver cyclase activity in the presence of glucagon^{1,36,76}; stimulatory effects of GDP have been reported also in the presence of ACTH on the adipocyte adenylate cyclase system⁷⁷. In view of these findings it is not clear that a GTPase turn-off mechanism^{78,79} (which necessarily requires that GDP binds tightly and acts only as inhibitor) can adequately explain the dynamic properties of all adenylate cyclase systems. Perhaps the difference in the properties of the turkey, liver and adipocyte systems is related to the lack of an oligomeric structure of RN in isolated turkey erythrocyte membranes.

The topographical relationship between the RN oligomers and C in the plasma membrane and the role of membrane lipids in this relationship remain unknown. Studies with phospholipases have shown that hormone action on adenylate cyclase remains intact even after 85% of the membrane phospholipids have been digested; substantial loss in action occurs only when a fraction of the remaining phospholipids is hydrolysed⁸⁰⁻⁸². These findings could mean that RN oligomers and C are in close proximity and possibly in selective domains of interacting phospholipids; the bulk of the phospholipids do not seem to be involved in assembly of the holoenzyme.

Generalisations and problems

If the notion is accepted that the effects of GTP on hormone binding to receptors are due to disaggregation of oligomers of receptors linked to N units, then the theory cited above may apply generally to all hormone-regulated systems that illustrate these effects, even those N units (N_x) not linked to adenylate cyclase. The latter include such GTP-affected receptors as angiotensin receptors in the adrenal medulla⁸⁴ and α -adrenergic receptors in liver⁸³ (see Table 2). Recent findings⁸⁵ that insulin activates a cyclic AMP-independent protein kinase in sarcolemma membranes by a process regulated by GTP is an interesting example of a potential N_x -mediated process unrelated to adenylate cyclase.

The possibility that different N units mediate the actions of hormones raises interesting new questions. Can the properties of the same receptor be modified by interaction with different types of N units? What determines the interactions of receptors with a particular type of N unit? The pertinence of these questions is exemplified by reports that catecholamines, acting through α -adrenergic receptors (by pharmacological criteria), both stimulate⁸⁶ and inhibit^{51,54} cyclic AMP production, and induce effects unrelated to adenylate cyclase activity⁸³. Other hormones exerting multiple effects on membrane processes

include adenosine⁴⁸⁻⁵⁰, dopamine^{53,87-89}, opiates⁹⁰⁻⁹², vasopressin^{93,94} and serotonin⁹⁵. Pharmacological studies (specificity, potency, antagonist or hormone binding to receptors) alone may not identify the type of receptor mediating these processes. Heterotropic effects of GTP on agonist binding indicate linkage of receptors to an N unit but do not identify the type of N unit. I have noted in Table 2 that certain RN complexes are affected by sodium ions, others by divalent cations, and that guanine nucleotides have different potencies on agonist binding. Perhaps such differences can be used to classify the N unit associated with the receptor. Clearly, what is necessary in future research in this area is to develop assay methods that identify unequivocally each type of N unit. Testing of biological effects is not necessarily the means of determining the type of RN unit. A bizarre example of problems encountered is the action of cholecystokinin on pancreatic acinar cells⁹⁶. In the cell the hormone stimulates zymogen secretion, calcium release and cyclic GMP production, but not the production of cyclic AMP; after breakage of the cell, the hormone stimulates adenylate cyclase in a GTP-dependent fashion.

Although other explanations are possible, these findings raise the possibility that 'redistribution' of receptors and N units occurs on cell breakage owing to the breakdown of stationary domains that normally segregate these units in the cell. 'Lateral domain redistribution' might be a physiologically regulated process due either to changes in the structural relationship of the cytoskeleton to the ordered domains or to propagated disturbances in the membrane structure. A possible example of the

latter is the report⁹⁷ that catecholamines, acting through a β -adrenergic receptor, stimulate a phospholipid methylating enzyme by a process which is affected by GTP but which does not involve the production of cyclic AMP; associated with methylation is an apparent 'flip' of the internally methylated lipids to the outer face of the membrane and a change in lipid microviscosity. Pleiotropic effects of the hormone could thus be generated by localised changes in lipid structure being propagated laterally and modifying the postulated domain structures of the membrane. In any event, these findings question the commonly held view that β -adrenergic receptors are singularly linked to stimulation of adenylate cyclase. Moreover, the dependency of the hormone effect on GTP suggests again the versatility of the N units in mediating the actions of hormones.

In conclusion, the classical notion of receptor alone controlling the events related to hormone and neurotransmitter action on adenylate cyclase is no longer valid. The constraining role of hormone receptors postulated here differs from the role of the receptor postulated in other theories of hormone action. More importantly, the theory places in perspective the role of another set of regulatory proteins (the N units) hitherto given relatively scant attention, particularly with regard to their apparent multiple and fundamental roles in the regulation of membrane-associated processes. I hope this rather brief article will stimulate investigation of the new problems to be faced in ascertaining both the structures of the GTP-regulatory proteins and how they function in the transduction of hormone binding at cell membrane receptors into physiological action.

Cometary collisions on the Moon and Mercury

Peter H. Schultz & Leonard J. Srnka*

Lunar and Planetary Institute, 3303 NASA Road 1, Houston, Texas 77058

Unusual swirl patterns of bright and dark material on the Moon and Mercury are proposed to be remnants of collisions with gas/dust-rich regions within a cometary coma. This interpretation provides important new clues for understanding cometary fine structure, impact effects of low-density material, and the origin of certain pronounced magnetic anomalies.

ALTHOUGH cometary impacts have long been assumed for inner Solar System bodies such as the Moon and Mercury^{1–3}, there has been little evidence for distinguishing such an event from a meteoroid impact. We propose that the enigmatic bright and dark swirls which cross portions of the lunar farside^{4,5} may be best explained by an impacting comet complex. The strong magnetisation of at least one swirl (Reiner γ) (ref. 6) and the close association of other swirls with lunar regions containing strong magnetic anomalies⁷ suggest that these features were magnetised in the impact. We argue that the swirls are young deposits, implying a recent cometary impact ($< 10^8$ yr ago) and ruling out an active lunar dynamo^{8–10} as the source of their magnetising field. Rather, this field may have been of cometary origin, perhaps amplified during the impact^{11,12}.

Bright/dark swirl patterns occur in three regions of the Moon. One of the best known examples is Reiner γ , which is near the western limb of the nearside (5° S, 60° W). The concentrations of patterns near Mare Marginis (15° N, 90° E) and Mare Ingenii (35° S, 180° E) are more impressive. Bright/dark swirls have not previously been studied in detail, but have generated several possible interpretations including nué ardente deposits¹³, antipodal effects of major basins⁴, volcanically derived sublimates⁴, secondary impact effects⁶, unusual secondary cratering phenomena associated with a cometary impact⁵, and selective preservation of albedo (crater rays) controlled by local enhancement of magnetic fields⁷. More detailed examination, however, reveals features that are suggestive of remnants of the impacting nuclear region of a comet.

Swirl patterns range in size from nearly 10 km to < 50 m across and form a variety of characteristic geometries: ribbon-like patterns, open loops and closed loops. As Fig. 1 shows, these patterns are commonly crossed by dark lanes. Both dark and bright patterns drape relief such as crater walls and rims and cross both the highlands and mare terrains (Fig. 2). At the highest resolutions available (~ 10 m), alteration of the surface (scouring) is not visible. Rather, the patterns represent diffuse brightening/darkening of unmodified terrains and commonly exhibit sharply defined boundaries over 50–100 m scales. In several examples, higher albedo regions correspond to sloped surfaces (for example, walls of degraded craters), whereas lower

albedo regions correspond to low-lying regions (for example, crater floor). Under high illumination, such patterns form a distinctive bright ring that strongly contrasts with other adjacent degraded craters. Ring patterns occur, however, in plains regions, not in association with changes in relief. Consequently, there may be several processes contributing to the formation of swirls.

Similar patterns are recognised on Mercury near latitude 20° N, 47° W and 4° N, 35° W. Because different phase angles and high-resolution images of these regions are unavailable, it is impossible to verify this identification in detail. Nevertheless, the bright loops and swirls noted at these locations are very similar to the gross patterns found on the Moon.

Although detailed photometry of the farside swirls is not available, several observations can be cited. Bright patterns occur on both dark (mare) and light (highland) surfaces. Apollo and Lunar Orbiter photographs under different illuminations and phase angles reveal that the bright patterns are strong forward reflectors (large phase angles) in contrast with most crater rays. This property, along with their characteristic pattern, make swirls easily identifiable. Dark lanes do not share this property, and under large phase angles, typically exhibit a reflectivity comparable to the surrounding terrains. Microdensitometer tracings reveal that the dark lanes are not simply an effect of contrast with the bright swirls, but exhibit a lower reflectivity under full illumination.

Longer wavelength measurements are available only for the nearside pattern, Reiner γ . Earth-based 70 cm (ref. 14) and 3.8 cm (ref. 15) radar data reveal no significant enhancements associated with Reiner γ . IR data during lunar eclipse¹⁶ reveal a possible 'cool region' that includes this pattern. Available data from the Apollo 17 Infrared Scanning Radiometer (ISR) provide much higher spatial resolutions (W. Mendell, personal communication) and also indicate no thermal enhancements. Consequently, Reiner γ exhibits a near-surface population of blocks resembling the average regolith. These data raise serious problems in the creation of a magnetic anomaly at this site, regardless of the proposed field source and remanence mechanism.

Swirl patterns are concentrated within two fan-shaped regions that open to the east (Fig. 3). Patterns near Mare Marginis converge near the 11-km diameter crater Goddard A, whereas patterns farther east converge near Mare Ingenii, perhaps

* Permanent address: Exxon Production Research Co., Houston, Texas 77001.

towards a fresh 8-km crater on the wall of O'Day. The Reiner γ patterns may represent an eastern extension of the latter system.

The areal coverage, fine structure and shape of swirls change with distance from the western convergent zone. Near Mare Marginis, the greatest areal coverage by swirls occurs within ~ 300 km of Goddard A. Individual patterns typically cover 400 km^2 . Beyond 300 km east of Goddard A, swirls exhibit finer patterns each typically covering $< 100 \text{ km}^2$. In contrast, swirls abruptly disappear beyond 250 km west of Goddard A. Figure 3 also reveals that characteristic pattern shape changes in relation to Goddard A. Swirls are broad, arcuate loops roughly concentric with Goddard A to the west, but form parallel patterns within 400 km east of Goddard A. At greater distances, individual patterns form tightly closed loops, rings and narrow ribbons.

Although individual swirl patterns cross highland relief, there seems to be some topographic control at both fine and broad scales beyond 400 km from Goddard A. At fine scales (< 20 km), bright rings encircle a dark interior and commonly coincide with medium-size craters (~ 10 – 20 km diameter) having smoothly sloping walls. At broader scales, swirl patterns cluster within large craters and basins such as Fleming, Ingenii, Van de Graaff and Aitken.

We argue that swirl patterns are very young features. They clearly overlay the well preserved farside craters King and Necho, and appear to cross rays from Giordano Bruno. Crater statistics for King crater¹⁷ reveal a production population down to craters at least 20 m in diameter, thereby indicating a very young age for the swirl patterns ($< 10^8$ yr). The stratigraphic relation with Goddard A, however, is more complex. West of this crater, rays appear to roughen or 'feather' the bright swirl patches and cross dark lanes. Nevertheless, swirl patterns clearly superimpose ejecta deposits elsewhere. Such relations suggest swirl formation contemporary with Goddard A.

Recency of swirl formation is also indicated by the general absence of small, subsequent craters that excavate underlying contrasting material. Important exceptions west of King Crater exhibit a highly unusual morphology: bright-rayed and dark-rayed subdued dimple craters. Similarly, clusters of small, rayed craters superpose sections of the ejecta facies of Goddard A. These exceptions may be related to impacting material associated with swirl formation.

The crossing of relief, the absence of visible surface scouring and the photometric/IR properties suggest that the swirl patterns represent either a deposit or a physical alteration of the uppermost regolith layers. The distribution and geometry of patterns suggest a relation with the formation of the crater Goddard A and an exogenic origin that is unrelated to secondary cratering. These observational constraints are consistent, however, with highly dispersed material impacting the surface before and soon after Goddard A. Such a sequence is expected for a cometary impact where the tenuous inner coma should both precede and follow impact by the nucleus by 50–100 s. More specifically, the swirls may represent remnants of collisions by gas/dust-rich zones within the inner coma. These zones may be fine-scale counterparts to the streamers and knots commonly observed in the inner nuclear regions of comets as a result of sporadic explosions of material (ices, solids and gases) from the nucleus¹⁸.

The detailed structures of the inner coma and inner nucleus regions are, however, poorly understood. Number densities of the primary parent molecules of a cometary atmosphere¹⁹ suggest that the total coma mass (gas plus dust) within 200 km of the nucleus could range between 10^9 and 10^{10} g (This value assumes an isotropic coma where the number density varies as the inverse square of the distance from the nucleus. The parent components are assumed to approximate values for Comet K where $\text{H}_2\text{O}:\text{C}:\text{C}_2:\text{CN}:\text{CH}_3\text{CN}:\text{HCN}$ relative abundances are 17:6:2:0.5:1.0(?):2(?), respectively. The absolute number density of H_2O is taken as 2×10^{11} for a production rate of 3×10^{29} molecules s^{-1} and a lifetime of 2×10^4 s. It is further assumed that the gas/dust ratio is unity.). If the swirls cor-

Fig. 1 *a*, Swirls 130 km west of King Crater at longitude 125° E, latitude 5° N showing characteristic looping pattern. Annulus of bright material at top coincides with a subdued crater. Arrow identifies ejecta from Necho crater that are crossed by dark lanes of the swirl patterns. Scale bar, 5 km. *b*, Swirl patterns overlapping rim of 23 km-diameter crater at longitude 110° E, latitude 11° N. Preservation on sloped surfaces suggests recent formation.

respond to gas/dust-rich zones, then this mass is not distributed isotropically, but is locally concentrated. Within 200 km of Goddard A, the total area covered by the swirls is $\sim 3,600 \text{ km}^2$, which represents nearly 10^5 km^3 . Thus, average mass densities in these zones may have ranged between 10^{-10} and $10^{-11} \text{ g cm}^{-3}$. Higher densities (10^{-8} – $10^{-9} \text{ g cm}^{-3}$) could be expected near the centre of major zones. Such values correspond to terrestrial atmospheric densities between altitudes of 90 and 120 km.

Although very tenuous, the derived gas densities are sufficient to heat, ablate and incinerate small meteors during entry into the Earth's atmosphere at velocities comparable to those expected, even for a low-speed cometary impact on the Moon ($\sim 20 \text{ km s}^{-1}$ ref. 4). This suggests that thermal alteration of the regolith may have occurred in the swirl areas and that the dynamic pressures (~ 0.1 bar) may have been sufficient to transport material on a micro-scale. Topographic control of reflected shock waves could locally enhance this process. In addition, if cometary dust particles are electrically charged and become confined within gas jets from the nucleus, their impact on the regolith at hypervelocities would generate an anomalous population of glasses and micrometre-sized iron particles. Both processes can alter the reflectance properties of the surface, which are sensitive to the mineralogy and petrology of the uppermost regolith²⁰. Consequently, the bright/dark swirl patterns are thought to represent high-velocity imprinting of the coma fine-structure by very fine-scale erosion/deposition and by the build-up of glassy materials through ablation of regolithic fine structure and impacts by cometary dust.

The recent discovery by Hood *et al.*⁶ that the nearside swirl feature Reiner γ coincides with a strong magnetic anomaly, and the suggestion that the swirls are generally in regions of strong remanent magnetic fields⁷ indicate that at least some of the lunar magnetic anomalies are of external origin, and are perhaps generated by cometary impact. Recent formation of these features precludes an origin by solar-wind stand off as proposed by Hood *et al.*⁶. Discussions of lunar anomalies must always treat two distinct problems: origin and strength of the magnetising field, and the nature of the remanence mechanism in the lunar rock which allowed a permanent magnetisation to be acquired^{21,22}. If remnant fields are associated with the swirls, only two courses are plausible for such a correlation: either the remanent fields predated the deposition, and merely served to guide the incoming coma material into a nonuniform pattern on the surface; or the field was present only during the emplacement of the deposits, during which time some remanence mechanism operated to generate the anomalies coincident with the swirls. In this case the magnetic fields are associated with the comet, or are generated during the impact¹².

The first hypothesis is untenable. To channel the plasma flow effectively, the remanent magnetic field B must exceed the value $B > (2\mu\rho)^{1/2}V$ at least one ion-gyro radius above the surface, where ρ and V are the mass density and flow velocity of the partially ionised coma gases, and μ_0 is the permeability of free space. Taking $V = 20 \text{ km s}^{-1}$ and $\rho = 10^{-10} \text{ g cm}^{-3}$ gives $B > 10^{-5} \text{ T} = 0.1 \text{ G}$. Since ρ may have been as large as $10^{-8} \text{ g cm}^{-3}$ in coma jets, lunar remanent fields of 0.1–1 G would have had to exist on large scales over the lunar surface at the time of the impact to channel the flow. Compression of the local field would ease this requirement somewhat, but not by more than an order of magnitude. As no evidence exists for broad-scale remanent field strengths of this magnitude on the moon, we reject this guided-plasma model.

Thus we argue that the remanent field now seen in swirls, such as Reiner γ , was acquired in the surface at the time of a comet

impact. It is likely that the magnetising field was intrinsic to the comet, perhaps generated in the nuclear region by a dynamo-like process²³ when the comet is close to the Sun ($< 1.5 \text{ AU}$) and thus very active, or simply due to the unipolar induction interaction of the coma with the solar magnetic field^{24–26}. In any case, the cometary field will probably be amplified as the coma is compressed against the lunar surface¹¹. However, the degree of amplification is not arbitrarily large, as current-driven plasma turbulence will create anomalous resistivity in the compressed region as the current density rises, and the electric fields will saturate. Although no data are available on field strengths in cometary comas, the poloidal field conversion model²⁵ gives values of 10^{-2} G , and allowing for the compression effects discussed by Gold and Soter¹¹, field strengths of 1–10 G should be present at the lunar surface during the impact for a considerable period. If the coma is $\sim 10^4 \text{ km}$ in size and hits the Moon at 20 km s^{-1} , large fields could be expected for times of the order of 10^3 s or more as the incoming tail continues to feed plasma and kinetic energy to the current systems flowing parallel to the lunar surface long after the nucleus has impacted. Apparently strong, relatively long-lived magnetic fields can be expected to be present at the lunar surface during such an event.

The critical problem in any impact-related generation of magnetic anomalies is the identification of a suitable remanence acquisition process. Shock remanence²⁷ is known to be effective in lunar surface materials when the shock pressures are in the range of 5–20 kbar. Such pressures are not likely to accompany swirl formation unless generated by individual microparticle impacts accompanying colliding gas/dust-rich regions. Moreover, these pressures could not be propagated beyond the rim region of the impact by the nucleus. Thermal remanence may be acquired if the jet of coma gas and dust impinging on the surface heats and alters the regolith in the presence of the ambient field. In this case each particle must cool through its Curie point while the field is still present. Such a process can occur if the impacting dust particles locally heat small volumes of

Fig. 2 Overview of region near Mare Marginis. Arrow identifies the crater Goddard A proposed to represent impact remnant of nucleus.

Fig. 3 *a*, Distribution of swirl patterns near Mare Marginis and farther east showing general concentration in a fan-shaped zone open to the east. Subarcuate patterns west of Goddard A (●) may represent hydrodynamic contact surface. Swirl patterns are proposed to be the result of fine-scale surface alteration by colliding gas/dust-rich regions within the inner coma. *b*, Distribution of swirl patterns near Mare Ingenii illustrating similar fan-shaped concentration. Reiner γ may be an eastern extension of this system.

soil, producing free iron droplets on a micrometre scale that cool in a fraction of a second and hence, acquire thermoremanence easily¹². However, it is difficult to explain specific features of the Reiner γ anomaly in this way. For example, the magnetisation direction for that swirl has a large component normal to the lunar surface⁶, whereas arguments based on a frozen-field MHD model suggests that the amplified cometary-field would be primarily tangent to the surface¹¹. However, the coma jet may have its own current system and magnetic field²³, in which case vertical fields may occur. A principal uncertainty is the inferred present surface strength of the remanent magnetic field at Reiner γ .

Using the data of Hood *et al.*⁶ and evidence that the swirl deposits are very thin (<1 m), we find a required regolith magnetisation I of $I > 0.8 \text{ e.m.u. g}^{-1}$ for a density of 2 g cm^{-3} , which exceeds by four orders of magnitude the stable component of remanence in lunar rocks, and by two orders the highest value of remanence observed in any lunar sample (G. W. Pearce, personal communication). This places severe constraints

on the composition of the regolith in the swirls. If we assume that the sampled lunar rocks constrain the remanence value in Reiner γ , then depths of alteration of 1 km or more are required to produce the Reiner γ magnetic anomaly. As the regolith depth of mare surfaces is <6 m, the remanence at Reiner γ must be much higher than any of the values yet found in the lunar samples. This demands either a very high free iron content, very high (perhaps saturation?) remanence in the iron grains, or both. The impacting coma gases (H_2O , CO_2 , and OH^-) also might alter the chemistry and mineralogy of the swirl areas, perhaps producing local concentrations of magnetite in the dark areas of the swirls.

If these interpretations are correct, then several statements can be made about the proposed comet. From scaling relations between crater diameter and impact energy²⁸, the size of Goddard A suggests a nucleus 200–500 m in diameter. Note that the resulting crater is not anomalous in appearance. The subarcuate patterns disappearing beyond 200 km west of Goddard A may correspond to a hydrodynamic contact surface,

which develops by collision of the sub-solar cometary atmosphere and the solar wind¹⁸. Broad swirls within 100 km of Goddard A correspond to the inner nuclear region of gases and dust, whereas the elongate and parallel patterns east of Goddard A delineate matter in the process of being swept into the flow patterns of the tail. Beyond 200 km from Goddard A, the remaining patterns indicate concentrations of gases controlled by magnetic field lines within the comet^{29,30} and/or by gases sublimating from ice bodies dislodged from the nucleus. The latter process could account for the unusual dimple-shaped bright and dark-rayed craters associated with certain deposits west of King crater. The general restriction of the swirl patterns within a fan-shaped zone reflects the projected form of the streamlined inner coma on the lunar globe. Clusters of small primary craters superposing the ejecta facies Goddard A and a few swirls suggest that a myriad of centimetre/metre-size meteoroids may have accompanied the event.

We take the correlation of a strong magnetic anomaly with one of the swirls, Reiner γ , as evidence for a strong magnetic field within the comet's coma. We suggest that the swirls which we have mapped on the lunar surface are generally magnetised due to thermoremanence or shock remanence (or both) in a highly altered lunar regolith, which has not been sampled by any lunar mission.

The distribution of swirls also may provide a clue to the direction of impact. The two major concentrations of swirls seem to be nearly symmetric about a line of latitude, thereby suggesting an orbit close to the ecliptic. A highly inclined orbit could result in a more asymmetric distribution. The east-open, fan-shaped envelope of deposits and the possible remnant of one impacting nucleus (Goddard A) suggest that the Moon must

have been in the waxing phase. Moreover, the relative timing between Goddard A and formation of the swirls requires that the tail of the comet was pointing away from the surface. From these considerations, the proposed comet would have been an incoming, prograde body. Such an orbit would reduce the relative impact velocity since the comet and the Earth-Moon system would be travelling in the same direction.

The excellent preservation of all swirl deposits, which appear to be surficial in character, may indicate formation by a single cometary system. A simple impact by one body does not seem possible owing to the separate Goddard A and Ingenii swirl concentrations. However, these patterns could result from a split cometary body, a common phenomenon¹⁸. Although not essential to our argument, Reiner γ also could be included in this system if it formed $3\frac{1}{2}$ days in advance of the Ingenii/Goddard A patterns. Rotation of the Moon during this time would geometrically allow the formation of Reiner γ beyond 180° from Goddard A.

Thus, it is plausible that a prograde, incoming, split comet system impacting the Moon between a waxing crescent and gibbous phases. Goddard A may represent the impact crater by a nucleus, whereas a small crater on the rim of O'Day may represent a second nucleus. The Reiner γ swirls could be part of the latter event, rather than a separate nuclear region. Although the most visible results are the swirl patterns, the unusual dark-rayed/bright-rayed dimple craters and a large number of small bright-rayed (non-secondary) craters near Mare Marginis may indicate an additional flux of small-size (<10 m) debris impacting nearly simultaneously.

This research was performed under a NASA contract with Universities Space Research Association.

Sequence of the human insulin gene

Graeme I. Bell, Raymond L. Pictet & William J. Rutter

The human insulin gene contains two intervening sequences, one is within the region transcribed into the 5'-untranslated segment of the mRNA and the other interrupts the C-peptide encoding region. A comparison of the human with the rat insulin genes indicates potential regulatory regions in the DNA segment preceding the gene and suggests that the ancestral form of the insulin gene had two intervening sequences.

DIABETES MELLITUS is a complex disease in which the primary clinical symptom is abnormally high fasting plasma glucose levels. In its many forms it may affect as much as 5% of the human population, and its incidence appears to be increasing¹.

The hormone insulin, isolated in 1922 by Banting and Best², regulates normal glucose homeostasis and also has other phy-

siological effects. Insulin appears to exert its biological activities through interaction with a receptor present on the membrane of most, if not all, cells³. This leads to a pleiotropic effect on several physiological processes including uptake of various nutrients, and enhanced synthesis of glycogen, lipids, certain amino acids and proteins⁴. In addition, it promotes proliferation of many

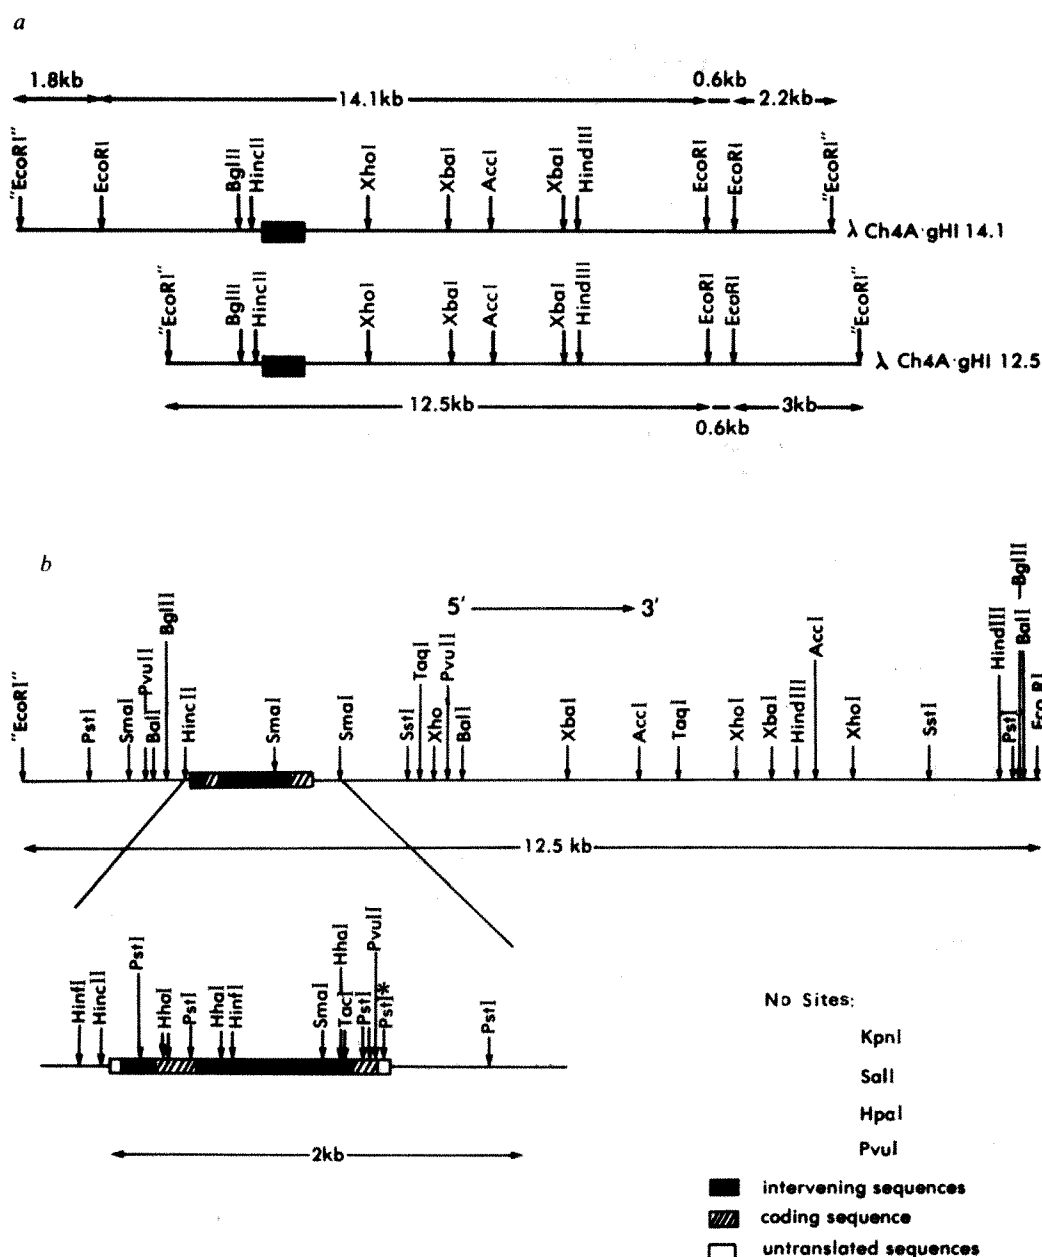

Fig. 1 a, Restriction maps of inserts of λ Charon 4A human insulin gene clones. A cloned library of approximately 20-kilobase fragments of human fetal liver DNA constructed as described by Lawn *et al.*²² was used. Plaques were screened for human insulin gene sequences as described previously¹⁹ by hybridisation with a nick-translated human insulin cDNA probe²¹. Phage containing the insulin gene were plaque purified and DNA was then prepared from phage grown in liquid culture. After digestion with *EcoRI* and agarose gel electrophoresis, the DNA fragments which contained insulin gene sequences were identified after hybridisation with human insulin cDNA²³. The order of the *EcoRI* fragments and the sites for other restriction enzymes within the human DNA inserts were determined by analysing multiple restriction enzyme digests¹⁹. The exact position of the insulin gene within the 12.5-kilobase (kb) *EcoRI* fragment of λ Charon 4A gHI 12.5, indicated by the box, was determined by more detailed restriction endonuclease mapping (b) and DNA sequencing. The position of the insulin gene in λ Charon 4A gHI 14.1 was inferred from the comparative restriction endonuclease analysis of the two clones. The *EcoRI* sites within quotation marks are those of the *EcoRI* linkers used in construction of the library and are adjacent to the λ arms. b, Partial restriction map of the human insulin gene and adjacent regions. The 12.5-kilobase insulin gene containing *EcoRI* fragment of λ Charon 4A gHI 12.5 was

subcloned into pBR322 (pGHI 12.5). The restriction sites were determined after single and multiple enzyme digests. The relative position of insulin coding sequences was determined by the hybridisation technique of Southern²³. The exact location and structure of the gene were determined by DNA sequencing. The orientation of the gene is indicated by the arrow.

animal cells in culture⁵. These processes may be mediated at least in part by an effect on the intracellular second messengers calcium and/or cyclic AMP⁶. Although administration of the hormone ameliorates the diabetic symptoms and allows a more or less normal life, diabetes and its complications are still the third leading cause of death in the US¹. The aetiology of diabetes is poorly understood; both environmental (dietary, viral and chemical) and genetic factors are involved^{1,7-9}.

Insulin has been isolated from a variety of vertebrate species^{10,11}. In all instances, the molecule is composed of two polypeptide chains (A and B) joined by disulphide linkages. In most species examined, there is only a single insulin and consequently, it is believed, a single gene. However, three species of rodents (laboratory rat, mouse, and spiny mouse) and two species of fish (tuna and toadfish) contain two distinct insulins^{11,12}, inferring the presence of two non-allelic insulin genes.

The immediate translation product of the insulin gene is a single polypeptide, preproinsulin, which contains a 'signal' peptide at the NH₂-terminus which facilitates the transit of the insulin precursor into the endoplasmic reticulum and is cleaved away during the process¹³⁻¹⁵. The resultant molecule, proinsulin, in which the peptides B and A are joined by the connecting C-peptide (NH₂-B-C-A-COOH), is the precursor of insulin¹⁶. The connecting peptide is believed to aid the formation of the appropriate conformation of the molecule and thus correct formation of the disulphide bridges. Consistent with this view, there is considerable variation in the structure of the C-peptide between species¹⁷.

Until recently there was no specific knowledge about insulin mRNA or the insulin gene. Using recombinant DNA methodology, we isolated a DNA complementary to the messenger RNA of rat insulin and determined its sequence¹⁸. The overall structure of rat preproinsulin was determined, and

Fig. 2 Strategy for sequencing human insulin gene and adjacent regions. End (5')-labelled restriction fragments were sequenced by the procedure of Maxam and Gilbert²⁴. The cleavage products were separated by electrophoresis in 0.38-mm thick 10% and 15% polyacrylamide gels. The direction and number of bases determined from each labelled restriction site are indicated. The coding regions of the gene are indicated by the boxes. The orientation of the gene and positions of the translational start and stop are also indicated. The number in parentheses is the position of the restriction site (Fig. 3) used to initiate a particular sequencing run. bp, Base pairs.

in addition, certain unknown amino acid sequences were established. The cloned insulin cDNA was used as a hybridisation probe to isolate fragments of genomic DNA containing the insulin genes^{19,20}. The genes encoding rat insulins I and II each contain an intervening sequence of 119 base pairs in the 5'-untranslated portion of the mRNA. In addition the rat insulin II gene (but not the rat insulin I gene) contains an intervening sequence (499 base pairs) in the region of the DNA coding for the C-peptide²⁰. Again using the rat cDNA as a probe to screen bacterial colonies containing recombinant plasmids derived from human insulinoma mRNA, we isolated a cDNA clone encoding human preproinsulin²¹. The nucleotide sequence of the human insulin mRNA is quite similar to the rat insulin mRNA. The human insulin cDNA was used as a probe to screen in turn for insulin sequences in a library of human genomic DNA fragments. We report here the complete sequence of the human insulin gene and the immediately adjacent DNA areas, and compare it to the rat insulin I and II genes.

Isolation and restriction endonuclease digestion mapping

The human gene library in bacteriophage λ Charon 4A described by Lawn *et al.*²² was obtained from Dr T. Maniatis. The library was constructed by partial digestion of human fetal liver DNA with *Hae*III and *Alu*I restriction endonucleases, size fractionation, methylation with the *Eco*RI methylase, *Eco*RI oligonucleotide linker addition, and cloning in the λ vector, Charon 4A. We screened the recombinant phages for those containing human insulin gene sequences by hybridisation with a radiolabelled cloned cDNA fragment encoding human preproinsulin²¹. Two out of approximately 10^6 phages hybridised with the probe. These two clones were purified and the DNA characterised. One clone (gHI 12.5) contained *Eco*RI fragments of 0.6, 3.0 and 12.5 kilobases, the other (gHI 14.1) contained *Eco*RI fragments of 0.6, 1.8, 2.2 and 14.1 kilobases. The largest *Eco*RI fragment in each isolate hybridised with the cloned insulin cDNA. Since the library was constructed from human DNA fragments obtained by essentially random cleavage, the data suggested that the two clones represent overlapping fragments of human DNA. Further restriction mapping confirmed this view and allowed ordering of the *Eco*RI fragments (Fig. 1a).

The 12.5-kilobase *Eco*RI fragment of gHI 12.5 was subcloned in the plasmid pBR322. A detailed restriction map of this fragment was constructed (Fig. 1b). The restriction mapping experiments indicated that the gene was not co-linear with the mature mRNA, since the extent of the coding regions was greater than the 416 base pairs present in the cloned human insulin cDNA used as a probe. Furthermore, the enzyme *Sma*I generated two fragments of 900 and 1,500 base pairs which hybridised with the cDNA probe. Since no *Sma*I sites were predicted by the mRNA sequence²¹, it seemed likely that the gene possessed an intervening sequence containing an *Sma*I site. The pattern and sizes of the *Pst*I fragments hybridising with the insulin cDNA were also consistent with the presence of an intervening sequence within the gene (see later Fig. 5).

Sequence and general organisation

The complete nucleotide sequence of the cloned human insulin gene, gHI 12.5, was determined by the procedure of Maxam and Gilbert²⁴. The strategy used is presented in Fig. 2. Insofar as possible both strands were sequenced and all restriction

Fig. 3 Sequence of human insulin gene and adjacent regions. The sequence of the human insulin gene and its translation into preproinsulin in one frame is presented. The 'Hogness' sequence, TATAAAG, is boxed. The putative 5'-end of the mRNA (capping site) is indicated by an asterisk, while the 3'-end of the mRNA (poly(A) addition site), is indicated by an arrow. The intervening sequences are indicated in parentheses and were positioned by comparison with the cDNA sequence of human insulin mRNA²¹ and the rat insulin genes^{19,20} and by using the GT/AG rule (see text). The last digit of the number is placed over the corresponding base.

cleavage sites were confirmed by sequence analysis with the exception of the *Xma*I site at position 1,247 (*Xma*I is an isoschizomer of *Sma*I) and the *Pvu*II site at position 1,596. This *Pvu*II site is within the coding region of the gene and the sequences on either side are co-linear with the mRNA sequence as determined from the cDNA clone. From restriction mapping experiments we are confident that no small fragments were missed. The sequence of the segment including the gene and adjacent regions (262 base pairs before and 97 base pairs after the gene) is presented in Fig. 3.

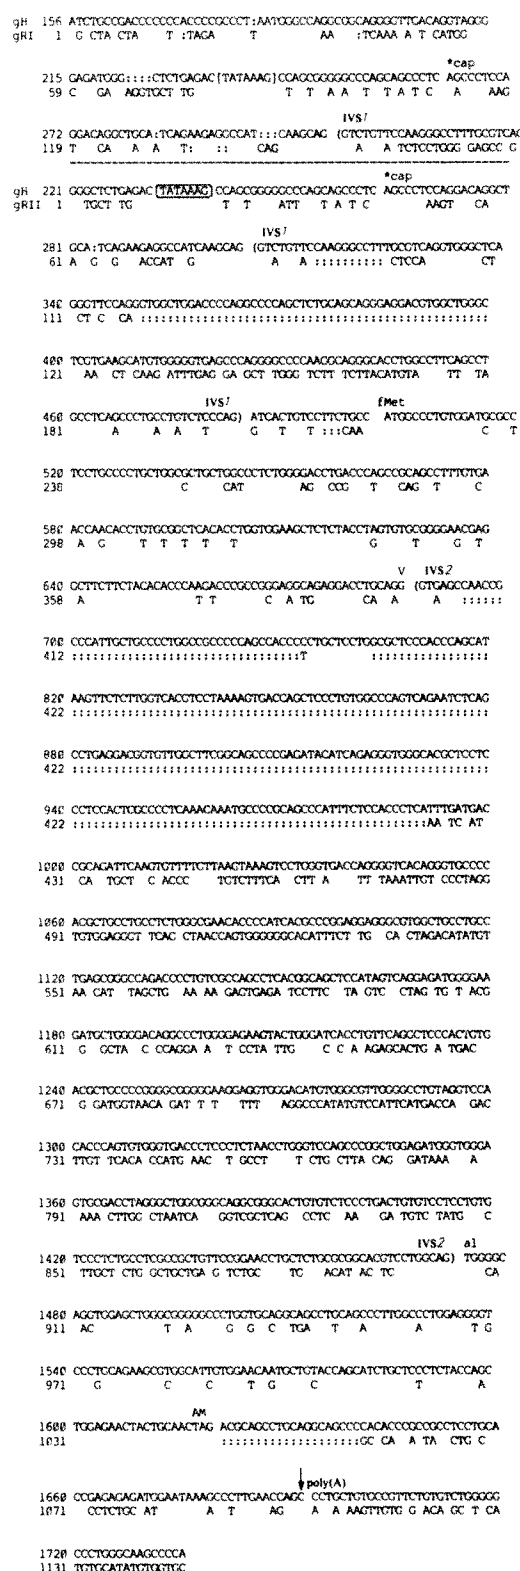

The nucleotide sequence in one reading frame predicts the amino acid sequence of human preproinsulin. It also establishes the presence of a 786-base pair intervening sequence within the DNA region encoding the C-peptide of proinsulin (IVS2). There is some ambiguity in the precise localisation of the intervening sequence. If one applies the GT/AG rule of Breathnach *et al.*²⁵ (GT at the 5' terminus, and AG at the 3' terminus of an intervening sequence), the intervening sequence occurs between the first and second nucleotides of the GUG which encodes Val 39 of proinsulin (Fig. 3). The rat insulin II gene possesses a shorter intervening sequence (499 base pairs) in exactly the same position²⁰; the rat insulin I gene lacks this intervening sequence^{19,20}. Besides the difference in length, there are other notable differences between the human and rat II intervening sequence (IVS2). In the human gene, the repeated boundary sequence is a trinucleotide, GTG, whereas in the rat II gene it is a dinucleotide, AG. There are three possible splicing points for the removal of the intervening sequence in the rat insulin II gene; there are only two possible splice points in the human gene. Except for the nucleotide sequence at the junctions, there is no extended homology between the intervening sequences of the human and rat II insulin genes (see below and Fig. 4).

The 416-base pair cloned cDNA of human insulin mRNA extends from 10 bases before the start of translation to the

poly(A) tract²¹. With the exception of the 786-base pair intervening sequence described above and two positions in the 3'-untranslated region of the gene, discussed below, the sequence of this gene is identical to the cDNA clone.

The structure of the 5'-untranslated region of human insulin mRNA could not be determined from the human insulin cDNA clone since the clone lacks most of this region. However, a comparison of the DNA sequence preceding the human insulin gene with the same region in the rat insulin I and II genes should define the 5'-end of human insulin mRNA, as well as localising any intervening sequences in this region. The results of such a homology study between the rat and human genes (Fig. 4) reveal

Fig. 4 Homology of the human insulin gene with the rat insulin I and II genes. The human insulin gene sequence (gH) (Fig. 3) is compared with the sequence of the rat genes for insulin I (gRI)¹⁹ and insulin II (gRII)²⁰. 'Maximum' homology was achieved by suitable additions, indicated in the sequence by colons, and by using a computer homology program. The program allows editing and moving of sequences while comparing one against the other. The detection of important homologies is facilitated with the Maxalig subprogram which finds the 15 best alignments between the two sequences being compared, showing the homology score for each, the size of the largest common cluster (contiguous sequence of matches) and the location of such a cluster. Another feature enables the user to select subsequences and work with these independently of the parent sequences. This may be carried out to any desired level to set subsequences of subsequences, and so on. This was used to obtain maximum homology by comparison of similar functional regions, for example, IVS1 of human and rat. The upper, continuous sequence is that of the human gene. The lower, discontinuous sequence indicates the nature of the differences between the human and rat genes. The absence of a nucleotide in the lower sequence indicates that the human and rat sequences are the same; the presence of a colon in either sequence indicates a gap equal in length to the number of colons to be added to achieve maximum homology. The Hogness sequence, TATAAAG, is boxed. The positions of the putative 5' end (capping site; *cap) and 3' end (poly(A) addition site; arrow, poly(A)) of the mRNA are indicated. The intervening sequences are indicated within parentheses and the left and right borders marked IVS1 or 2, respectively. The occurrence of IVS2 between the first and second base of the valine codon at proinsulin amino acid position 39 is indicated by a 'V' at the left hand boundary and 'al' at the right. The initiation codon for preproinsulin is designated 'fMet'. The numbers in the left margin refer to the human sequence (numbered according to Fig. 3) and the rat I or II sequence numbered according to refs 19 or 20, respectively. The upper panel presents the homology of the human insulin gene with the rat insulin I gene in the region before the first intervening sequence (IVS1), and the lower panel the entire homology of the human insulin gene with that of rat insulin II.

three regions of sequence homology in the 5' portion of the gene. The human and rat I genes (the rat II gene sequence does not extend this far²⁰) are homologous around nucleotide 186 of the human sequence (numbers are derived from the sequence in Fig. 3) and preceding a presumptive transcriptional initiation site. The second region (nucleotides 231–310) is centred around the 'Hogness sequence' TATAAAG (positions 233–239); no other TATAAAG-like sequence occurs in the 1,789 base pairs which have been sequenced. In the rat insulin genes, this region of homology includes the 5'-end (capping site) of the mRNA, the 43 bases corresponding to the 5'-untranslated portion of the

Fig. 5 Comparison of *Pst*I digestions of human insulin gene isolates gHI 12.5 and gHI 14.1. After *Pst*I digestion the DNA fragments were separated by electrophoresis in reversibly cross-linked 6% acrylamide–1% agarose gels²⁸. The fragments were transferred to nitrocellulose and hybridised with labelled human insulin cDNA. The size of hybridising fragments in base pairs are indicated. 'Ori' (origin) is the top of the gel. The lanes are *Pst*I digestions of *a*, human insulin cDNA clone, pCHI-1²¹; *b*, human insulin genome clone, gHI 12.5; *c*, human insulin genome clone, gHI 14.1. From the sequence (Fig. 3) and restriction mapping the order of *Pst*I fragments in lane *b* is (in base pairs) 5'–307, 834 (27) 85, 500–3'. The 27-base pair fragment is not seen as it migrated too rapidly.

mRNA as well as the 5'-boundary of intervening sequence 1 (IVS1). The extensive homology present in this segment (Fig. 4) suggests it contains the cognate region of the human insulin gene. Therefore, we tentatively assign the A at position 263 (Fig. 3) as the 5'-end of the mRNA. This is 24 base pairs after the end of the TATAAAG sequence. The start of the intervening

sequence is 43 base pairs after this A residue in the rat II gene. Taking into account the homology and applying the GT/AG rule, this segment of the human insulin gene is only 42 base pairs long. It therefore appears that a similar intervening sequence occurs in the human insulin gene with its boundary at guanosine 305 (G-305). The third region of homology in this section of the gene is centred at nucleotide 483, 17 base pairs before the ATG which encodes the fMet of preproinsulin. This undoubtedly corresponds to the 3'-boundary of the intervening sequence which began at G-305. Thus, the human insulin gene contains an intervening sequence of 179 base pairs in the DNA segment encoding the 5'-untranslated region of insulin mRNA; this is 60 base pairs longer than the 119-base pair intervening sequence in the rat insulin genes. In the human gene the 3'-border of this intervening sequence is 3 base pairs further from the fMet encoding ATG as compared to the corresponding sequence in the rat genes.

Thus the 5'-untranslated region of human insulin mRNA is 59 nucleotides; in rat insulin mRNA, it is 57. Both human and rat insulin genes contain an intervening sequence of different length in the DNA which encodes this portion of the mRNA, although the exact position from the boundaries of the leader segment are slightly different. The sequence reiterated at the boundaries is different between the two species as is the number of splicing frames (human: 4; rat: 5). As observed for IVS2 in the C-peptide region there is no obvious homology between this intervening DNA segment (IVS1) in the human and rat genes except at the boundaries.

In contrast to the substantial nucleotide sequence homology between the rat and human insulin genes evident in the 5' flanking region, the coding regions, and the 21 bases at the end of the 3'-untranslated region before the poly(A) site, there is no homology in the region extending further in the 3' direction.

Finally, the 1,789-base pair segment which contains the gene and adjacent regions is very GC-rich. The mean molar GC content of human DNA is 38.0% (ref. 26), whereas this segment has a content of 64.8%. The high GC content is uniformly present in all regions sequenced. The rat insulin genes also have a GC composition of 55%, which is greater than rat DNA, 40% (ref. 27).

Allelic variation

Restriction endonuclease analysis of the two human insulin gene isolates demonstrated a *Pst*I site in gHI 12.5 (Fig. 5, lane *b*) which is absent in gHI 14.1 (Fig. 5, lane *c*). Clone gHI 14.1 possesses a 585-base pair fragment instead of the 500- and 85-base pair fragments of gHI 12.5. The nucleotide sequence of the insulin gene of gHI 12.5 indicates that this additional *Pst*I site is centred at nucleotide 1,628 in the portion of the gene encoding the 3'-untranslated region of the mRNA. There are also two differences between the sequence of the human insulin cDNA clone, cHI-1 (ref. 21), and the genomic clone, gHI 12.5 in this region (Fig. 6); a C to T transition at nucleotide 1,628 which results in a *Pst*I site in gHI 12.5, and a C to A transversion at nucleotide 1,641. It is difficult to exclude the possibility that the differences observed in the cloned cDNA did not occur during cDNA synthesis. Nevertheless, the similarity in the restriction maps of the two genome isolates outside the insulin gene region (Fig. 1a) suggests that the observed differences reflect allelic variation. Furthermore, this interpretation indicates that the individual from whom the DNA was obtained for cloning was heterozygous since insulin sequencing as well as genetic studies²⁹ suggest only a single insulin gene per haploid genome complement.

Structural features

Present models of eukaryotic transcription propose that the primary transcript (pre-mRNA), which is co-linear with the DNA, is capped and polyadenylated before removal of any intervening sequences^{30,31}. Messenger RNA biosynthesis can be

regulated at any of these steps. If the signals for these processes are dependent upon the primary structure of the DNA or RNA, the features common to both the human and rat insulin genes may indicate regulatory regions conserved during evolution.

As indicated in Fig. 4, there are two regions of sequence homology in the DNA segment preceding the sequence encoding the 5'-terminus of the mRNA. One region is around the sequence TATAAAG (G239), 24 base pairs before the start of transcription. This sequence is thought to interact with RNA polymerase to facilitate initiation of transcription³⁰. The other region is centred at A 184, 77 base pairs in front of the capping site. In the human but not the rat insulin gene this region is also part of a quite large imperfect palindrome (positions 155–213). A similar palindrome but of different sequence is present in mouse α -globin³² but not in the mouse β -globin genes^{33,34}. Since structures of this type in bacterial genes are often involved in the interaction with regulatory proteins³⁵, the human gene palindrome may also be a binding site for an insulin-specific regulatory protein.

Fig. 6 Comparison of the sequence of the DNA region encoding the 3'-untranslated portion of insulin mRNA of gHI 12.5 (a) and cHI 1 (b). The sequence differences are indicated. The single *PvuII* site within the gene (gHI 12.5) or cDNA (cHI 1)²¹ was labelled with [γ -³²P]ATP and polynucleotide kinase. After secondary restriction enzyme digestion, the 5'-end-labelled fragments were sequenced by the procedure of Maxam and Gilbert²⁴. The chemical cleavage products were separated by electrophoresis in a 0.38-mm thick 15% polyacrylamide gel.

There are a number of direct repeat sequences located in the region immediately preceding the TATAAAG sequence. The sequences GGAAATT (positions 119–124 and 131–136), CC(G or C)ACCCC (positions 162–169 and 170–177), and GG(T or C)AGGGG (positions 195–202 and 209–216) each occur twice while the sequence CAGCC (positions 139–143, 145–149, and 152–156) occurs three times. Also, the sequence at the 5'-end of the mRNA, AGCCCTC (positions 263–269), is repeated immediately upstream at positions 256–262. The 5'-terminus of the silk fibroin mRNA is also repeated in a similar manner³⁶. Since most of these features are only characteristic of the human insulin gene and are not observed in the rat insulin genes, their physiological significance is not known. However,

since there are two insulin genes in rat and only one in human, some aspects of control may be different.

There is no obvious homology between the human and rat genes in the DNA sequence to the 3' side of the common 21-base pair sequence surrounding the AAUAAA sequence at the end of the insulin mRNA. Hence, if there are regulatory signals which occur 3' distal to this point, they are not a common feature of the insulin genes.

Fig. 7 Schematic comparison of human and rat insulin genes. The topology of the two rat insulin genes (I and II) and the single human insulin gene is displayed. The coding sequences for the peptide chains (pre-, B, C and A) of preproinsulin are represented by the clear boxes. Intervening sequences (IVS) are distinguished by the shaded areas with the length of each intervening sequence indicated below. The extent and position of nucleotide homology between intervening sequences of the two species is represented by the size of the asterisks—the larger the asterisk the greater the homology. Vertical lines describe the positions at which intervening sequences occur. The internal intervening sequence in the rat II and the human gene occurs in exactly the same position (valine 39 of the C-peptide region) whereas the position of the intervening sequence located in the 5'-untranslated region is displaced by three nucleotides in the human gene as compared with both rat genes. Also indicated are the sites for polyadenylation and capping (shown by arrows) as well as the Hogness box, a potential site for the initiation of transcription (indicated by the small black box). The arrow indicates the direction of transcription.

The signals in the nucleotide sequence which direct the capping and intervening sequence excision reactions are not obvious. However, as observed for other mRNAs²⁰, the 5'-untranslated region of the human insulin mRNA does possess some elements of secondary structure, whose possible regulatory role, if any, is undetermined. From a comparison of the similar regions of other genes, both the intervening sequences in the human insulin gene conform with the GT/AG rule proposed by Breathnach *et al.*²⁵. Also, as there are several ways in which each intervening sequence can be removed and still preserve the sequence of the mRNA (see ref. 37 for review), the structure(s) of the pre-mRNA molecule which affect intervening sequence removal remain elusive. The conservation of sequence homology around the boundaries of intervening sequences of the rat and human insulin genes suggest that the sequences of this region might be important. This homology is most extensive on the 5' side of the splice point, that is, before the GT at the 5' and the AG at the 3' borders of the intervening sequences. However, these features are not evident in comparisons between the rabbit and mouse β -globin genes³⁸.

Discussion

There now appear to be at least two types of mammalian insulin gene. The genes for human and rat II have two intervening sequences, while rat I has a single intervening sequence (Fig. 7). All three contain an intervening sequence in the DNA which encodes the 5'-untranslated or leader position of insulin mRNA. The position of this intervening sequence is the same in the rat I and II genes, but is displaced by 3 base pairs in the human gene. The human and rat II insulin genes contain an additional intervening sequence at exactly the same position in the C-peptide encoding region of the gene. The similarity in the structure of the human and the rat II insulin genes suggests that the ancestral mammalian insulin gene will contain two intervening sequences. It has been assumed that the human haploid genome contains a single insulin gene since only one insulin protein has been isolated. The two independent isolates of the human insulin gene described here have identical restriction endonuclease maps (Fig. 1a) in the region outside the gene. This is not usually the case for non-allelic genes, for example the rat I and II insulin genes^{19,20}. The two human insulin gene isolates, however, differ by at least one base change which results in the elimination of a *Pst*I site in the region corresponding to the 3'-untranslated portion of the mRNA. These data indicate that the clones represent alleles of a single insulin gene. Data from experiments on a mutant form of insulin which results in diabetes²⁹ as well as studies on familial hyperproinsulinaemia³⁹ are consistent with this hypothesis and furthermore indicate co-dominant expression of the two alleles of a diploid heterozygote. In rats and presumably in other species with two insulin genes, the single gene was duplicated and at least in rats has lost one of the intervening sequences. The mechanism of elimination of the intervening sequence from the rat I gene must have been precise since the amino acid sequence and nucleotide sequence around the splice have been conserved. Although the gene sequences which encode human and rat insulin mRNA and several sequences before the gene are highly conserved, the internal regions of the intervening sequences of these genes are highly divergent. In fact, so much so that it is difficult by homology studies to discern any meaningful regions of homology within the internal regions of the intervening sequence and therefore impossible to deduce anything about the evolution of these portions of the insulin gene or the cause of their different sizes.

Evidence from viral systems suggests that at least one intervening sequence in the mRNA precursor is necessary for normal mRNA accumulation⁴⁰. This would indicate a requirement for one intervening sequence in the insulin gene. The role of additional intervening sequences in insulin and other genes is unknown. In the case of rat insulins the additional sequence does

not substantially affect biosynthesis since both rat insulins are present in approximately equal proportions^{41,42}. It is interesting, however, that it is present in that region of the gene which encodes the most variable portion of the molecule (the C-peptide), yet Gln and Val adjacent to the splice have been highly conserved. Moreover, the region around the splice has been deleted in the insulin related proteins, insulin growth factors I and II and relaxin¹⁷. An examination of the genes for these proteins as well as the insulin genes of lower vertebrates might give us insight into the structure of the primordial gene.

The causes of diabetes are still poorly understood. The disease can be classified into insulin-dependent and -independent forms. The insulin-dependent form of the disease may result from a destruction of the insulin-producing β cells by chemicals or viral infection^{8,9}. However at least in one instance this form of the disease is the consequence of a mutated insulin²⁹. Its study by Tager *et al.*²⁹ established a genetic basis for this form of the disease in some individuals and, moreover, that both human insulin alleles are expressed. In the other, more common form of the disease, insulin-independent or maturity-onset, there is a pronounced correlation between family history and diabetes^{1,7}. Thus there can be a genetic component associated with both forms of the disease. The allelic differences observed in the 3'-untranslated region of human insulin mRNA are a form of polymorphism which is not manifested in the structure of the protein but could affect insulin biosynthesis. This form of allelism might be especially relevant if it occurred in functionally important regions of the gene or mRNA, for example, the DNA region around that encoding the 5'-end of the mRNA. Presumably in normal metabolic conditions, insulin biosynthesis might be unaffected, however under metabolic stress there could be a profound effect on insulin synthesis which could result in diabetes. This hypothesis can be tested by examining the insulin genes of diabetic individuals to determine if they possess alterations. Moreover the extensive nucleotide sequence conservation between human and rat insulin genes in regions outside those encoding preproinsulin immediately suggests those regions which should be examined for their possible role in the regulation of insulin biosynthesis. These analyses as well as surrogate genetic techniques, in which normal or *in vitro* mutated insulin genes are introduced into cultured cells or *Xenopus* oocytes, should increase our understanding of the genetic factors which regulate insulin biosynthesis.

We thank Dr Hugo Martinez for developing the computer programs which facilitated the handling and analysis of the data, Margarita Quiroga for technical assistance, and Leslie Spector and Sonja Bock for assistance in preparing the manuscript. In pancreatic islets a peptide corresponding to the C-terminal tetrapeptide amide of cholecystokinin and gastrin, Trp-Met-Asp-Phe-NH₂, is present in nerve terminals. This tetrapeptide amide is uniquely potent as a releaser of insulin and the other islet hormones, whereas larger cholecystokinins and gastrins as well as tetrapeptide analogues are considerably less potent. We suggest that neural release of the tetrapeptide amide is implicated in regulation of pancreatic hormone secretion.

HORMONAL peptides may also serve important roles as neuroregulators. The related gut hormones, gastrin and cholecystokinin (CCK), belong to this group of peptides. They are located in central¹⁻⁶ and peripheral nerves^{6,7}, synthesised in neuronal tissue⁸, and concentrated in synaptic vesicles from which they are released like other neurotransmitters⁹.

Recently we studied the distribution and molecular nature of CCK in peripheral nerves⁶, and in continuation of these studies we have observed CCK nerve terminals in pancreatic islets. The predominant form of CCK in these nerves seems to be the C-terminal tetrapeptide amide, Trp-Met-Asp-Phe-NH₂, common to CCK and gastrin, hereafter referred to as CCK-4. We have also examined the effect of various cholecystokinins and gastrins on the isolated, perfused pancreas and observed that CCK-4 was considerably more effective in releasing insulin than larger molecular forms of gastrin and CCK, confirming our earlier impressions in man¹⁰. The results suggest that the secretion of insulin and other islet hormones is under neural control by the tetrapeptide amide.

Structure of CCK and the application of antisera specific for different CCK sequences

CCK is closely related to gastrin both structurally and functionally. The hormones probably share a common evolutionary origin⁴. Their identical C-terminal sequence (Fig. 1) is responsible for their biological activity, and the remaining parts of the molecules modify their potency on different target tissues. Both hormones are synthesised and released as a range of molecules of different sizes and biological potencies^{2,11-16}. Because of this molecular heterogeneity and as the common sequence appears highly immunogenic, characterisation of CCK immunoreactivity by conventional radioimmunoassays and conventional immunocytochemistry is insufficient. We have, therefore, developed a range of antisera specific for different sequences of CCK-33 and gastrin-17 (Fig. 1); details of their production and characterisation have been described previously¹⁷⁻¹⁹. These antisera have proved valuable for the characterisation of CCK and gastrin cells^{4,19,20} and in identifying the molecular nature of gastrin and CCK in extracts of nervous tissue^{1,2} and in cerebrospinal fluid²¹. In the present study we have used the antisera

to examine the localisation and molecular nature of the pancreatic CCK/gastrin-like peptides. Moreover, we have studied the activity of different molecular forms of CCK and gastrin on pancreatic secretion.

Structure-activity relationship of the cholecystokinins and the islet-cell secretion

The effect of different molecular forms of CCK on the release of insulin and the other islet hormones was studied by perfusion of the isolated, porcine pancreas. The concentration of insulin, glucagon, somatostatin and pancreatic polypeptide in the effluent was determined by sensitive and specific radioimmunoassays, whose development and character have been described in detail previously²²⁻²⁵. We chose the porcine pancreas to study the effect of gut hormonal peptides²⁶, because the pig is the only species for which the structure of most gut hormones, including CCK, is known. The perfusion technique and the reliability of this *in vitro* model has been reported in detail previously^{26,27}.

The cholecystokinins stimulated the secretion of all pancreatic hormones in a dose-related manner (Fig. 2). CCK-4 was by far the most potent peptide. Even at the lowest concentration (10^{-10} M), CCK-4 was a powerful secretagogue. The intact tetrapeptide amide with free Trp- and -Phe-NH₂ termini seemed necessary for the activity. Thus, synthetic peptides with NH₂-terminal modifications, such as removal of tryptophan (CCK-3), extension by glycine (CCK-5, gastrin pentapeptide) or by BOC- β -alanine (Peptavlon) greatly reduced the secretagogue activity. C-terminal modifications also reduced the potency. Thus, the deamidated tetrapeptide, Trp-Met-Asp-Phe-OH, stimulated insulin secretion only at the highest concentration tested (10^{-6} M), and it was without effect on glucagon, somatostatin and pancreatic polypeptide secretion (Fig. 3).

The larger molecular forms, CCK-8 and CCK-33, were significantly less potent stimulators of the endocrine pancreas (Fig. 2). As the tetrapeptide amide constitutes the active site also of the gastrins, we compared the effect of CCK-4 with the

principal molecular form of the gastrin, the heptadecapeptide amide gastrin-17 which, likewise, was several-fold less potent than CCK-4 (Fig. 2). In contrast to their weak effects on the endocrine pancreas, the larger hormonal peptides (CCK-8, CCK-33 and gastrin-17) were all more effective than CCK-4 in stimulating exocrine, pancreatic secretion (Table 1). This observation is consistent with the absence of innervation of the exocrine pancreas by CCK nerves (Figs 4 and 5).

Innervation of the pancreatic islets by cholecystokinin nerves

The immunocytochemical studies were conducted on pancreatic tissues from pig, cat and hamster. Antisera specific for the C-terminus common to CCK and gastrin revealed immunoreactive nerves occurring in two distinct locations: islets and ganglia (Figs 4 and 5). These nerves enter the pancreas in large trunks which also contain numerous non-immunoreactive fibres. In contrast to the smooth fibres observed in nerve trunks, those occurring in and around ganglia and islets had a beaded appearance, suggestive of axon terminals with varicosities. The widespread distribution of immunoreactive nerves within the pancreatic islets and ganglia suggests a true innervation of the endocrine cell populations. The failure to detect immunoreactive nerve cell bodies in the pancreas, as well as the strong innervation of the ganglionic cells, suggests an extrinsic source for the nerves.

Our attempts to demonstrate the nerves with C-terminal-specific antisera were guided by previous observations on brain tissue showing that the CCK nerves contained a preponderance of a C-terminal tetrapeptide-like component^{2,6,28} which was detected only by these antisera⁶. The immunocytochemical results were corroborated by absorption controls showing that only peptides containing the C-terminal tetrapeptide amide sequence were able to inhibit the staining reaction (compare Fig.

Fig. 1 The amino acid sequences of porcine cholecystokinin (left) and gastrin (right). The largest molecular form of CCK with known structure is a nonatriacontapeptide amide (CCK-39)^{36,37}. Molecular forms larger than CCK-39 have been found in nervous tissue and intestinal mucosa^{1-3,11}. These forms² have an additional extension at the NH₂-terminus of CCK-39. The amino acid sequence of the NH₂-terminal extension (R_{comp.1}) is not yet known. The largest molecular form of gastrin with known structure is a tetratriacontapeptide amide (gastrin-34)³⁸. A molecular form larger than gastrin-34, component I, has been found in serum¹⁴, gastrointestinal mucosa³⁹, the pituitary¹ and the vagal nerve⁷. Gastrin component I corresponds to gastrin-34 with an NH₂-terminal extension. The amino acid sequence of this extension, (R_{comp.1}) is not yet known. The shaded amino acid residues indicate the common C-terminal tetrapeptide amide sequence of CCK and gastrin. The arrows indicate points of tryptic cleavage. The brackets indicate the specificities of the antisera. Production and characterisation of these antisera have been described previously^{2,18}.

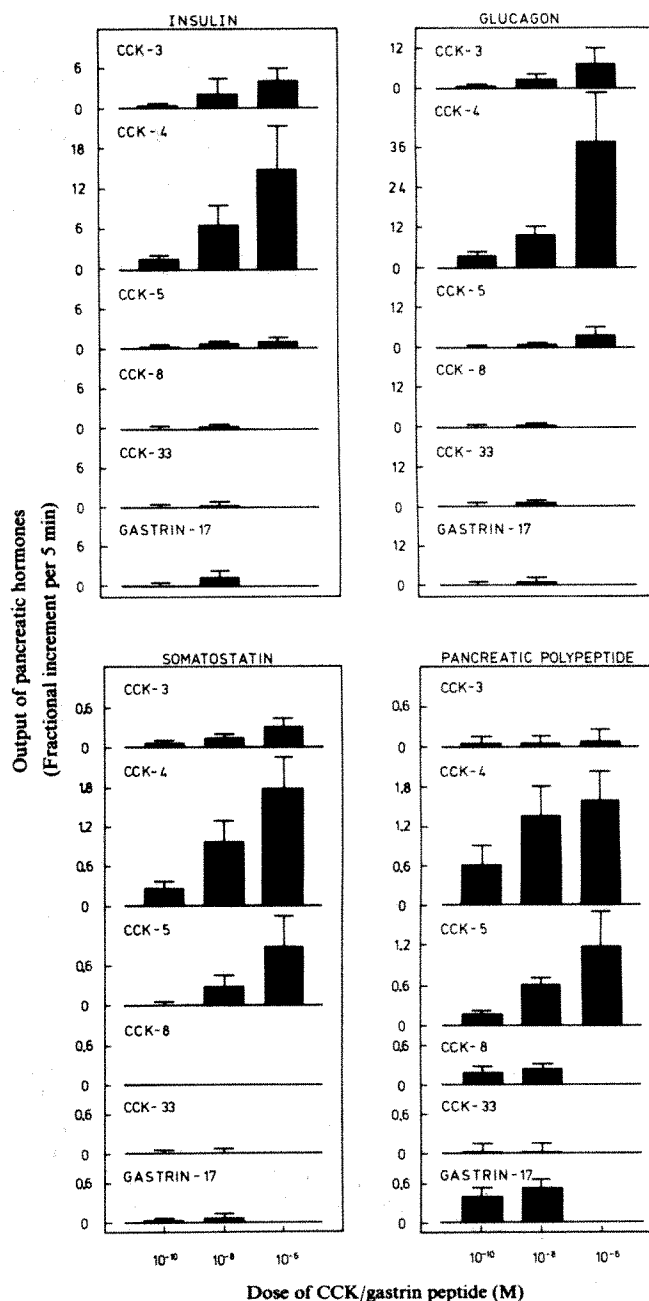

Fig. 2 Secretion of insulin, glucagon, somatostatin and pancreatic polypeptide from the isolated perfused, porcine pancreas in response to 5-minute stimulations with CCK and gastrin peptides. The CCK/gastrin peptides were administered in concentrations of 10^{-10} , 10^{-8} and 10^{-6} M. The mean (\pm s.e.m.) incremental hormone output (\sim fold increase) above the output in the corresponding 5-min prestimulatory period was calculated. Each dose of each peptide was administered in seven perfusion experiments, except CCK-4, which was given during 11 perfusion experiments. CCK-3, -4, -5 and -8 correspond to the COOH-terminal tri-, tetra-, penta- and octapeptide amide of CCK-33. The preparation and technique for the perfusion experiments have been described in detail previously^{25,26}. In the present experiments the glucose concentration in the perfusate was 5–7 mM. The response of the four pancreatic hormones to stimulation with gastrin and CCK peptides showed only little dependency of the glucose concentration in the perfusion medium within the 5–7 mmolar range. Studies of the effect of other large molecular forms of gastrin and CCK (gastrin-34, gastrin-14 and CCK-39) will be reported elsewhere (Jensen, S.L. *et al.*, in preparation).

4). Thus, a system of pancreatic nerves, storing either the free tetrapeptide amide or peptides containing this sequence, appear to innervate both the islet parenchyma and ganglia.

Attempts to localise the immunoreactive material at the ultrastructural level were unsuccessful. Embedding of formaldehyde-fixed tissue in resins or paraffin abolished immunoreactivity. Hence, post-embedding staining²⁹ was not possible.

Table 1 Exocrine secretion (ml h⁻¹, mean and range) from the isolated perfused porcine pancreas during stimulation with CCK/gastrin peptides

	Preperiod	10 ⁻¹⁰ M	Preperiod	10 ⁻⁸ M	n
CCK-4	0.15 (0–1.1)	0.1 (0–0.9)	0.1 (0–0.48)	1.2 (0.48–2.28)	11
CCK-8	0.1 (0.1–1.2)	1.5 (0.96–3.60)	0.2 (0.1–0.4)	6.0 (3.0–6.0)	7
CCK-33	0.1 (0–0.3)	2.2 (0.1–3.3)	0.6 (0–0.6)	6.0 (2.4–9.0)	8
Gastrin-17 (s)*	0.3 (0.2–0.9)	2.4 (1.0–4.8)	0.4 (0.1–1.3)	10.8 (5.0–14.1)	10

* (s), sulphated variant.

Instead we stained cryostat sections, which subsequently were embedded in Epon-812. Ultrathin sections revealed nerve terminals containing stained vesicles of varying diameters. The significance of this result is doubtful in view of the difficulties in carrying out appropriate controls on equivalent sections.

Apart from the nerves described above the pancreas also contains scattered endocrine cells displaying C-terminal gastrin-CCK immunoreactivity. Such cells were numerous in the feline

pancreas, scarce in the hamster pancreas and absent from the pig pancreas. As shown in a previous study, these immunoreactive cells also react with gastrin-specific, but not with CCK-specific antisera, and they are distinct from islet D (somatostatin) cells³⁰. In the feline pancreas, these cells occur in both ducts and islets, and are also scattered in the exocrine parenchyma. In the hamster, rare immunoreactive cells were confined to the ducts and exocrine parenchyma. Recent double staining experiments

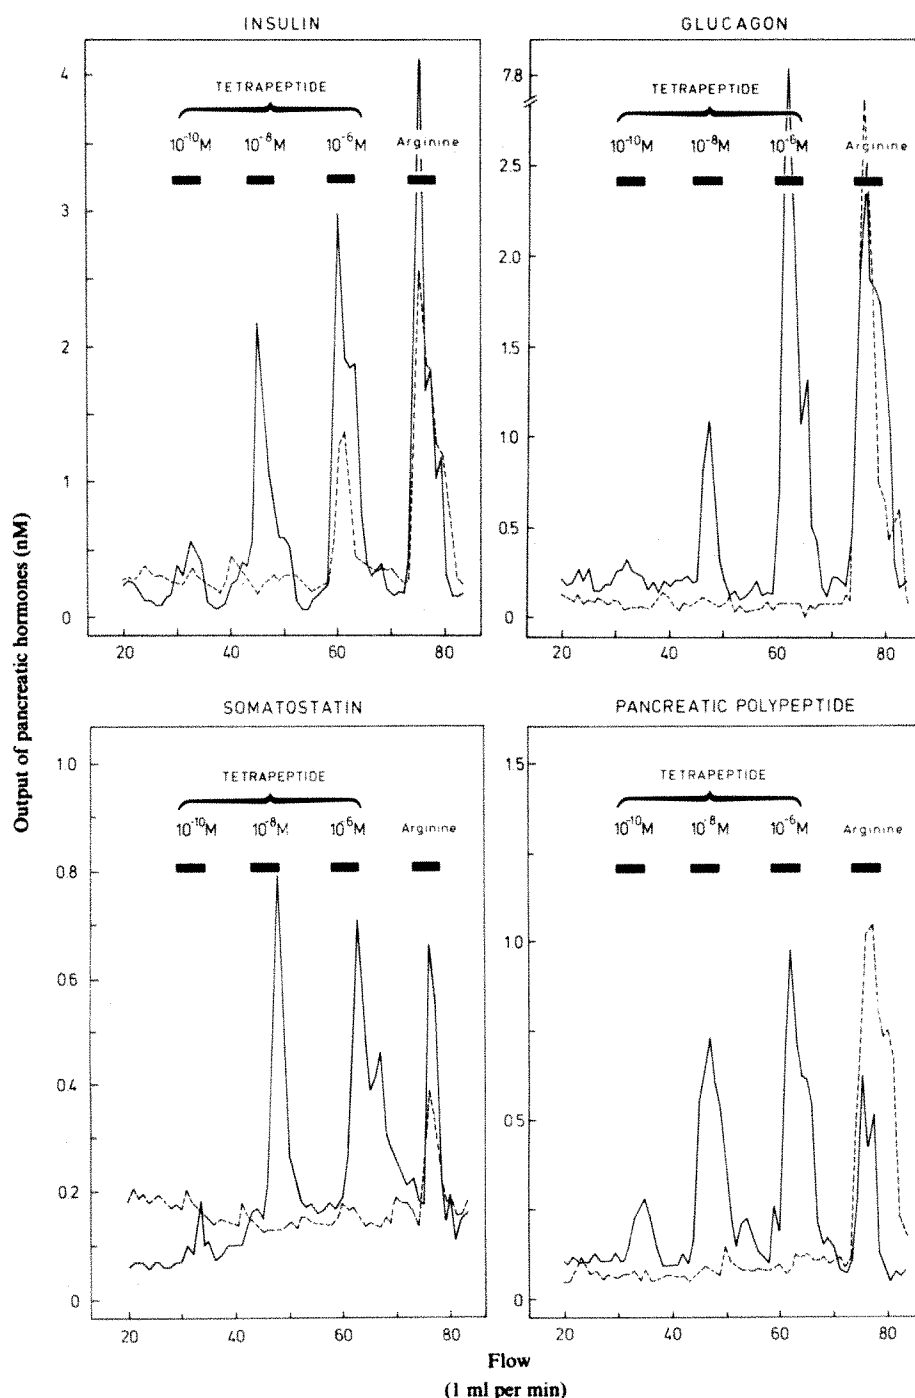

Fig. 3 Secretion of insulin, glucagon, somatostatin and pancreatic polypeptide from the isolated, perfused porcine pancreas in response to 5-min stimulations with the intact tetrapeptide amide (Trp-Met-Asp-Phe-NH₂; solid line) and with the deamidated tetrapeptide (Trp-Met-Asp-Phe-OH; broken line). Each line represents a typical perfusion experiment in which the tetrapeptide was administered in the three doses indicated. CCK-4 was given in 11 experiments (for mean output and s.e.m., see Fig. 2), and the deamidated tetrapeptide in four experiments, all with results as shown above. Each perfusion experiment was terminated by a 5-min stimulation with L-arginine (5 mM) to control optimal function of the preparation. For further details about technique, see refs 26 and 27.

Fig. 4 Sections of cat pancreatic islets stained with antiserum 4562, recognising the common C-terminal tetrapeptide amide of cholecystokinin and gastrin, Trp-Met-Asp-Phe-NH₂. In *a*, the site of antigen-antibody reaction has been revealed with the peroxidase-antiperoxidase (PAP) method of Sternberger^{6,29}, whereas in *b* indirect immunofluorescence has been used ($\times 295$). Note the occurrence of numerous varicose immunoreactive nerve terminals, which surround the islet cells in an innervation-like pattern (arrows). Adult, freely fed cats ($n = 10$), hamsters ($n = 10$) and pigs ($n = 1$) were studied. The pig pancreas was perfused in situ with a 4% paraformaldehyde solution in 0.1 M sodium phosphate buffer pH 7.3, following cessation of stimulation experiments. Pancreatic slices were dissected out, postfixed in the same fixative for 1–2 h and rinsed in 20% sucrose in 0.1 M sodium phosphate buffer pH 7.3, overnight. Cats and hamsters were anaesthetised (mebumal/chloralose) and perfused via the heart with the formaldehyde solution. Following postfixation and rinsing in sucrose all pancreatic specimens were frozen in melting Freon 22 and sectioned in a cryostat. Immunocytochemical staining was carried out with antisera as described elsewhere⁶. The site of antigen-antibody reaction was revealed by immunofluorescence or by the peroxidase-antiperoxidase (PAP) procedure^{6,29}. Controls included conventional staining controls²⁹ as well as absorption controls including pretreatment of the antisera for 24 h at 4 °C with 100 μ g per ml diluted antiserum of *a*, pentagastrin (ICI); *b*, synthetic human gastrin I (ICI); *c*, synthetic caerulein (Farmatolia); and *d*, 99% pure porcine CCK-33 (V. Mutt). Absorptions against these peptides, but not against peptides lacking the common COOH-terminal tetrapeptide sequence (vasoactive intestinal polypeptide, substance P, ACTH, somatostatin) abolished staining. *c*, Section of hamster islet stained by indirect immunofluorescence as in *b*. Weak unspecific fluorescence (autofluorescence) is noted in the zymogen cells at the periphery of the islets. Unlike the fluorescence of the islet nerves, this fluorescence remains in control sections.

(for technical details, see ref. 31) in cat pancreas have now shown that the CCK nerves are primarily associated with glucagon cells in the islets.

The molecular nature of cholecystokinin in the pancreas

We extracted pancreatic specimens only from adult mammals in which we had ascertained that the immunoreactivity was located exclusively or almost exclusively in nerves, that is, hamsters and hogs. Porcine pancreatic tissue was obtained from a local abattoir 20 min post mortem. Hamster pancreas was dissected from anaesthetised animals. The tissue was immediately frozen at -70°C until extraction. Samples of frozen tissue weighing 0.5 to 2 g were immersed in boiling water (0.1 g ml^{-1} , pH 6.6), boiled for 20 min, homogenised and centrifuged (2,000g, 20 min). After decanting the first supernatant the pellet was extracted with 0.5 M acetic acid for a further 15 min at 4 °C, followed by homogenisation and centrifugation (2,000g, 20 min). The water and acetic acid supernatants were applied to calibrated Sephadex columns (Fig. 6).

The chromatography, monitored by the different radioimmunoassays, disclosed the presence of five different molecular forms of CCK in the porcine pancreas (Fig. 6). The component with the largest molecular weight eluted in a position before CCK-39, and immediately after the void volume. The next three components eluted in positions corresponding to those of CCK-33, the C-terminal dodecapeptide of CCK (CCK-12), and the C-terminal octapeptide of CCK (CCK-8). Finally, a fifth component eluted at a position corresponding to the C-terminal tetrapeptide amide (CCK-4). When synthetic CCK-4 was used as standard for measurement of the fifth component, this component was seen to be far more abundant than the remaining CCK components (Fig. 6c). Apart from the immunoreactivity corresponding to CCK-4, specific gastrin immunoreactivity was not found in the porcine extracts. The nature of the different CCK-components was corroborated by re-chromatography on Sephadex G-50 and G-25 columns and by chromatography with a urea gradient. Using appropriate standards (CCK-33 for components I and II; CCK-8 for III and IV; and CCK-4 for V) the following concentrations of each component (I–V) were found: 1.2 ± 0.5 , 0.3 ± 0.1 , 1.5 ± 0.7 , 3.2 ± 1.1 and 19.6 ± 7.1 pmol per g porcine pancreas (mean \pm s.e.m., $n = 4$). Extracts of pancreas for hamsters contained less immunoreactivity, but again the predominant component corresponded to CCK-4. An additional component eluting in a position corresponding to heptadecapeptide gastrin was assumed to have originated from the scarce endocrine gastrin cells in the hamster pancreas.

Several lines of evidence support the contention that the fifth component described above is identical to CCK-4: (1) The

Fig. 5 Section of cat pancreas reacted with As 4562 in the indirect immunofluorescence procedure. Numerous preterminal nerves are seen to enter an intrapancreatic ganglion and to innervate non-immunoreactive ganglionic cell bodies (asterisk) ($\times 350$).

Fig. 6 Gel chromatography of extracts from the porcine pancreas, in which all cholecystokinin/gastrin immunoreactivity was confined to nerve fibres. Specimens of pancreatic tissue were obtained 20 min post mortem and immediately frozen. While frozen the tissue was cut in pieces weighing a few mg. The pieces were immersed in boiling water, for 20 min (0.1 g ml^{-1}), and subsequently homogenised for 5 min. After centrifugation, samples of the supernatant (panel *a* of the figure) were applied to calibrated Sephadex G-50 superfine columns ($10 \times 1,000 \text{ mm}$) eluted at 4°C with 0.02 M veronal buffer $\text{pH } 8.4$, at a flow rate of 4 ml per h . After decantation of the first supernatant, the pellet was extracted by 0.5 M acetic acid and rehomogenised for 5 min. After centrifugation, samples of the acid supernatant (panel *b*) was applied to columns calibrated and eluted as described above. The elutions of the boiled water extracts as well as the acetic acid extracts were monitored by four different radioimmunoassays, whose development and character has been described in detail elsewhere¹⁸. The first (upper) diagram in panel *a* and *b* illustrates the elution pattern as measured with CCK antiserum 4478, specific for sequence 20–25 of CCK-33 (see Fig. 1). The second diagram in panels *a* and *b* illustrates the elution pattern using CCK-antiserum 4698, specific for sequence 30–33 of CCK-33 (see Fig. 1). The third diagram in panels *a* and *b* illustrates the elution pattern using gastrin antiserum 2609, specific for sequence 30–33 of CCK-33 (see Fig. 1). Monoiodinated ^{125}I -CCK-33 (ref. 18) was used as tracer and porcine CCK-33 as standard for the three mentioned antisera. The fourth (lower) diagram in panels *a* and *b* illustrates the elution pattern as measured with the gastrin-specific antiserum no. 2604 (ref. 17) used for further control of the specificity. Antiserum 2604 shows a negligible cross-reactivity with CCK when monoiodinated gastrin-17 was used as tracer⁴⁰. Synthetic human gastrin-17 was used as standard with antiserum 2604. Panel *c* illustrates the Sephadex G-50 elution pattern of the boiled water extract as monitored by the assay using antiserum 2609 and ^{125}I -CCK-33. Panel *c* thus corresponds to the third diagram in panel *a*, the difference being that synthetic CCK-4 was used as standard instead of CCK-33 for measurement of the immunoreactivity eluted in the position corresponding to that of CCK-4. Note the difference in order of concentration (1:5) on the ordinates of panel *a* and panel *c*. (For further details on the immunoreactivities of different molecular forms of CCK, see refs 18 and 28.)

component was detected only with gastrin antisera which are specific for the tetrapeptide amide sequence common to gastrin and CCK (Fig. 1, 4–6). These antisera are highly sensitive to modifications of the tetrapeptide amide structure. Deamidation, removal of NH_2 -terminal tryptophyl residue, exchanges or insertions of other amino acids almost abolish the antibody binding (unpublished results). Thus, a C-terminal tripeptide amide would not be detectable. (2) The component eluted in a position corresponding to that of synthetic CCK-4 in different gel chromatographic systems. (3) The extracts contained the complementary NH_2 -terminal fragment of CCK-8, detected by antiserum 4698, which is specific for the sequence¹⁸, Asp-Tyr-(SO_3H)-Met-Gly (Fig. 1). The presence of a peptide resembling this NH_2 -terminal fragment suggests that the C-terminal peptide is produced by cleavage of CCK-8, and that it has a size corresponding to the tetrapeptide amide, as a larger C-terminal peptide, would require a smaller and hardly detectable NH_2 -terminal fragment.

The molecular forms of CCK in extracts of porcine pancreas correspond to the components in extracts of porcine nervous and intestinal tissue². The CCK-4-like component also predominates in these tissues^{28,32}. The predominance suggests that CCK-4 is the main product of the immunoreactive nerves in the pancreas. This accords with the demonstration of islet nerves with antisera specific for the C-terminus and with the weak and inconsistent staining of the islet nerves with antisera specific for other sequences of CCK-33. The larger components are presumably biosynthetic precursors in accordance with the biosynthetic relationship found for the different molecular forms of CCK in rat cerebral cortex^{8,33}.

Discussion

Our results suggest that CCK-4 (Trip-Met-Asp-Phe- NH_2) is present in CCK nerves in the pancreas and is involved in the regulation of islet cell functions. The present results, as well as those from previous studies in man¹⁰, show that CCK-4 has an immediate and potent effect on islet cell secretion.

The origin of the CCK-containing nerves in the pancreatic islets is unknown. However, CCK nerves are present in many regions of the body. Thus, we have reported that human and porcine brains contain CCK in quantities 10 to 100 times greater than those of other brain peptides^{1,2}; and that cerebral CCK is located in nerves in most regions of the central nervous system⁶. We have also found that the CCK in cerebral neurones fulfils several of the criteria for neurotransmitter function^{6,8,33}. In guinea pigs CCK is present in peripheral nerves which are particularly abundant in the muscular wall of colon⁶. We also observed a high density of CCK nerves in the coeliac-superior mesenteric ganglion⁶. The predominant molecular form of CCK in the peripheral nervous system corresponded mainly to CCK-4 (ref. 6). The pancreatic CCK nerves reported here correspond to the latter type.

Because of the high frequency of diabetes mellitus in man, the pancreatic CCK nerves are of considerable clinical interest. We have previously observed that CCK-4 is a potent insulin releaser in man¹⁰, suggesting that human islet cells may also possess receptors for CCK-4. As CCK-4-like peptides also occur in the human central nervous system and gut^{2,28,32}, it is likely that CCK-4 may also act as a neurotransmitter or neurohormone in the human pancreas. In view of the potent effect of CCK-4 on insulin secretion and possibly also on β -cell growth^{34,35} it may be

that CCK-4 or a suitable analogue may be of value in the treatment of insulin-dependent diabetes mellitus.

The low latitude ($b = 2.8^\circ$) radio source CTB80 (ref. 1) is a probable, albeit unusual, supernova remnant² (SNR). A compact high brightness region with a very flat spectrum dominates its centre, and we find optical emission associated with this feature. Here we discuss evidence that CTB80 may be young, and in particular the possibility that it was observed in China at the beginning of the fifteenth century.

CTB80 is seen to best advantage in Fig. 1, a photographic representation of the 49-cm map made with the Westerbork Synthesis Radio Telescope (WSRT). Its radio emission is clearly the result of synchrotron radiation: the spectrum is nonthermal and large areas of the source are polarised. As unusual as the irregular morphology may seem, the most remarkable feature is the bright central peak with its flat radio spectrum. Notwithstanding an estimated spectral index $\alpha \approx 0$ between 49 and 6 cm, the fact that it is significantly polarised establishes its non-thermal nature.

We find that the nebulosity is most prominent on the E (or 'red') Palomar Sky Survey plate coinciding with the flat spectrum peak (Fig. 2). The agreement in both position and extent of the optical emission and flat spectrum radio component makes it highly probable that they are related. The only other nebulosity which might be associated with CTB80 is a narrow filament located some 10 arc min away from the prominent features, roughly along and aligned with the northern edge of the south-west radio ridge.

The lack of detailed radio-optical coincidence, which may be a feature of young SNR³, suggests that CTB80 could be of recent origin. Another, probably more direct indication of recent activity is the central flat spectrum component which with its morphology is somewhat reminiscent of the Crab Nebula⁴, or 3C58 (ref. 5). There have been several recent attempts^{6,7} to define and investigate the centre-filled or 'plethoric'⁸ SNRs as a separate class. Although CTB80 is more like G326.3–1.8 (ref. 9) than other members of this class, comprising as it does both compact, flat and extended, steep spectrum emission, it is perhaps worth considering whether it, too, might belong to the group. Weiler and Panagia⁷ argue that such SNRs are maintained for a relatively short period of time (10^4 yr) by a pulsar as in the Crab itself, after which their flat spectrum emission dies rapidly away. However, there does not seem to be a realistic pulsar candidate for CTB80: PSR1946+35 and 1952+29 lie too far away, about 3° north and south of it, respectively¹⁰, and a recent observation detected no scintillating component¹¹.

As far as the age of CTB80 is concerned, the purely morphological evidence is not decisive. While the irregular outer structure might suggest an old, well expanded object interacting with its environs, it could be argued that this is indicative of very recent activity, the form of the extended radio emission still dominated by the dynamics of the outburst which produced it. As noted above, the lack of corresponding optical nebulosity argues against an extremely old remnant with much swept-up material.

Table 1 Positions relevant to the new star of 1408

Object	α (1950.0)	δ (1950.0)
17 Cyg (south-east end of Niandao)	19 h 45 min	+33°37'
CTB80 nebulosity	19 51	+32 45
Cyg X-1	19 56	+35 04

But it is probably the compact, central component, whose flat spectrum suggests relative youth, which holds the key to this mysterious object. The fact that its spectrum shows no high frequency cut-off to 5 GHz enables us to set an age limit, depending on the magnetic field strength. For an equipartition field the value obtained, not greater than a few times 10^4 yr, is

* Permanent address: Radio Astronomy Centre, Tata Institute of Fundamental Research, Ootacamund, India.

not especially valuable. If its age is 10^3 yr, then assuming that obscuration does not prevent our observing nebulosity near the centre of CTB80, there is a slight possibility that there is an historical record of the supernova. We have therefore examined a list of pre-telescopic supernova candidates compiled by Clark and Stephenson¹², and find that of their 75 events, only one is within 40° of CTB80.

Li Qi-bin¹³ has recently corrected the date of this guest star to 24 October 1408, shows that there may be nine Chinese references to it, and convincingly argues that it was a supernova. Li also suggests that it was the progenitor of the X-ray source (and black hole candidate) Cyg X-1, while we feel that an association with CTB80 is at least as likely. The only meaningful position, given in three of the chronicles, relates the new star to the Chinese constellation Niandao. This linear asterism runs from north-west to south-east, terminating at the latter end in 17 Cyg. A literal interpretation of the (translated) text, "to the southeast of Niandao", suggests a position both south and east of 17 Cyg (like that indicated by Clark and Stephenson¹²), consistent with CTB80 but excluding Cyg X-1 (Table 1). A looser interpretation of the wording would probably include anything within several degrees of 17 Cyg, and hence both candidate objects.

An indirect reason for preferring an association between CTB80 and the star of 1408 is that on both observational and theoretical grounds we expect supernovae to produce SNRs, and Cyg X-1 has no associated extended radio emission. One also wonders whether a supernova explosion would not have disrupted the binary system to which Cyg X-1 belongs. Although these arguments are somewhat weakened by the fact that we do not know what the event responsible for Cyg X-1 might have looked like, we will continue our discussion assuming that an association with CTB80 is more likely. What are the consequences of this assumption?

We concur with Li's conclusion that the star of 1408 must have been bright. (In addition to the reasons he gives, note that the description in the 'Ming Shilu' means that the star was probably observed just after sunset and before the end of

Fig. 1 A shaded contour photographic representation of the brightness distribution observed in CTB80 at 49 cm wavelength made with a 1 by 2 arc min beam. +, The highest peak, a flat spectrum compact component at the western end of the plateau; x, the positions of two strong sources which have been subtracted. North is at the top, and centre is $\alpha = 19^{\text{h}} 51.6^{\text{m}}$, $\delta = 32^\circ 49'$. Scale bar, 20 arc min.

Fig. 2 An enlargement of the Palomar Sky Survey E plate (Copyright National Geographic Society-Palomar Sky Survey), showing the main nebulosity near the centre of CTB80. In the inset the optical emission has been sketched on a contour plot of the 6 cm map of the flat spectrum component made with a 7 by 13 arc s beam. The most prominent optical feature is the knot of emission near the western edge, elongated in position angle 80° . From prints made with various exposures it is clear that there are no sharp emission features and that although diffuse nebulosity probably fills the entire radio emitting region, there appears to be a hole in the centre. Scale bar, 20 arc s.

astronomical twilight.) The chronicles consistently describe it as 'like a lamp', wording similar to that used for the supernova of 1572 ('large as a lamp') when its apparent magnitude was -3.5 mag (ref. 12). The lack of European reference to the 1408 star suggests that it was not as bright as the supernova of 1006 which did arouse interest¹². We conclude that the peak magnitude was probably -4 ± 1 mag. In a recent optical and radio investigation, Angerhofer *et al.*¹⁴ conclude that the likely distance to CTB80 is 3 ± 1 kpc, with at least 3–4 mag of absorption. If the maximum absolute magnitude of the supernova was -19 mag we would expect an apparent magnitude of -3.1 mag, in reasonable agreement with our above estimate for the 1408 star.

The spectral data obtained by Angerhofer *et al.*¹⁴ are consistent with a shell expanding at 35 km s^{-1} . If the distance (3 kpc) and age (570 yr) suggested above are correct, the shell has expanded at an average speed of 375 km s^{-1} . This is not irreconcilable with the spectral data if there has been substantial deceleration. Alternatively, the nebulosity may be excited circumstellar gas like the quasi-stationary flocculi in Cas A (ref 15).

Average velocities required in the outermost parts of the radio source are substantially higher, however. The optical wisp south-west of the main nebulosity must have travelled at some $13,000 \text{ km s}^{-1}$ since 1408, and the speed of material at the very edges of the radio emission would have to be at least four times higher. All of this assumes that a single outburst was the cause of CTB80 in its entirety, which may not be a necessary condition.

Apart from the possibility that we are seeing two totally unrelated sources juxtaposed (which we consider quite unlikely), we have no evidence which contradicts the notion that the outer arcs and ridges are the result of activity before 1408.

Despite the substantial body of data collected there is clearly much work to be done if we are to achieve a good understanding of this perplexing object. It does seem plausible that CTB80 is a young supernova remnant located within a few kiloparsecs of the Sun. Although it exhibits a superficial similarity to remnants like the Crab Nebula, its morphological and other properties make it unique among galactic nonthermal objects.

We thank Dr M. R. Kundu for his interest and involvement. R. G. S. thanks Drs A. G. de Bruyn and J. R. Dickel for helpful comments. We acknowledge the contribution of Dr S. van den Bergh. The Westerbork Synthesis Radio Telescope is operated by the Netherlands Foundation for Radio Astronomy with financial support from the Netherlands Organisation for the Advancement of Pure Research (ZWO).

Photoelectrochemical properties of metalloporphyrins

F. J. Kampas, K. Yamashita* & J. Fajer

Department of Energy and Environment, Brookhaven National Laboratory, Upton, New York 11973

The photovoltaic responses of *meso* tetraphenyl-, *meso* tetrapropyl- and octaethyl-porphyrins, porphines, chlorins, cofacial diporphyrins and mesoporphyrin IX diesters were investigated using two cell configurations:

Al|Porphyrin|Ag, and Al|Porphyrin|Fe(CN)₆³⁻, Fe(CN)₆⁴⁻|Pt.

We found (1) that the Al–porphyrin interface is photoactive: the action spectra closely follow the absorption spectra of the porphyrins, and this interface is best described as a semiconductor–insulator–metal diode consisting of porphyrin|Al₂O₃|Al; (2) that within a homologous series, in which the porphyrin skeleton is fixed but the metal is varied, the quantum yields parallel the ease of oxidation of the porphyrin in nonaqueous solvents. The more easily oxidised compounds exhibit the higher quantum yields; (3) no obvious correlations are found with the luminescent properties of the porphyrins in solution; (4) the morphology of the films influences the quantum yields: amorphous films are better than microcrystalline ones; and (5) the most efficient cells reach quantum yields of ~0.2 and energy efficiencies of ~1% for monochromatic light at the peak of the action spectrum in the region of 400–450 nm.

*Permanent address: Hiroshima University, Hiroshima, Japan.

Although attempts to build photovoltaic and photoelectrochemical devices sensitised by dyes have met with varying degrees of success^{1–14}, the high quantum yields and energy efficiencies recently reported^{15–17} for the primary photoprocesses in photosynthetic organisms have stimulated a renewed interest in artificial systems based on chlorophyll derivatives. The inherent chemical fragility of chlorophyll and bacteriochlorophyll *in vitro* has focused attention on synthetic porphyrins, whose physical and chemical properties can be readily tailored by varying their metal and/or their organic framework. Examples of these are the recent reports of photovoltaic cells based on phthalocyanine^{18,19} and porphyrin²⁰ films sandwiched between metals of low work functions, such as aluminium or indium, and metals of high work function, silver or gold. These cells generate open circuit voltages (V_{oc}) of several tenths of a volt with short circuit currents of microamperes, and quantum

Fig. 1 Comparison of the optical spectrum of a magnesium tetraphenylporphyrin film with the action spectra, obtained for the cell shown, on illumination of the Al/porphyrin and Pt/electrolyte/porphyrin electrodes. Note the large differences in photocurrent quantum yields at the two interfaces.

yields as high as 0.1. The Al–dye (or In–dye) interfaces exhibit rectifying behaviours attributed to Schottky barriers induced by interaction of the p-type semiconductor dyes with the metals. A similar cell, which used zinc tetraphenylporphyrin layers on Al and a solution of ferri–ferro cyanide as ohmic contact, was reported by Wang²¹ to generate $V_{oc} > 1$ V and two such cells in series oxidised water to oxygen.

To assess the effects of metal and substituents, we have screened the photoresponses of a large number of porphyrin derivatives.

Figure 1 compares the photocurrent quantum yield obtained for a sublimed film of magnesium tetraphenylporphyrin (MgTPP) in a Wang cell with the optical spectrum of the porphyrin film. The large differences in photocurrent obtained on irradiation of the two electrodes and the similarity of the action spectrum at the Al electrode to the absorption spectrum of the porphyrin, clearly indicate that the Al–porphyrin interface is the photoactive region. Similar results are obtained with films deposited by rapid evaporation of concentrated solutions of dyes except that the absorption bands of the films are less diffuse and resemble solution spectra. Although the Al–porphyrin interface has been characterised²⁰ as a Schottky

barrier, the dark current-voltage behaviour of the cells suggests that the electrode assembly exhibits the properties of a metal-insulator-semiconductor diode²² (Fig. 2).

The significant effects of ligand and metal variations are illustrated in Table 1. Peak quantum yield (calculated for short circuit currents obtained on illumination through the semi-transparent aluminium electrode at the Soret absorption band of the porphyrins) ranged from 10^{-1} to 10^{-4} at wavelengths between 400 and 450 nm. Films prepared by rapid evaporation of solutions using a photoresist spinner were ~50% more effective than films prepared by sublimation. The latter were found to be microcrystalline by electron microscopy at 20,000-fold magnification while the former appeared amorphous.

For a given porphyrinic ligand, the quantum efficiencies of the photocurrents paralleled the first oxidation potential of the porphyrin (Fig. 3) but all porphyrins did not fall on the same curve. Octaethylporphyrins, for example, were less efficient than other porphyrins. This may be due to a combination of packing, extent of overlap that facilitates exciton migration, and the property of this class of porphyrins to form dimeric dications²³ on oxidation which may act as electron traps. The significant effects of substituent groups on the photovoltaic properties were especially evident in the poor response of the mesoporphyrin IX diesters where the long aliphatic chains may

prevent good π - π overlap between the porphyrin rings and act as insulators towards electron transport. Although dimeric chlorophylls and bacteriochlorophylls are thought^{16,17} to act as the phototaps and primary donors in photosynthetic systems, synthetic diporphyrins were less effective than monomers in the cells considered here.

No obvious correlations were discerned between quantum yield and the luminescent properties of the porphyrins in solution. The platinum and palladium complexes, which decay²⁴ exclusively from excited states via triplets were not exceptional

† Quantum yield is defined as electrons produced per photon incident on the porphyrin film at low light intensities. Because of the high optical density of the films at the wavelengths used (absorbances between 1 and 2), the number of photons absorbed is nearly equal ($\pm 10\%$) to the number of photons incident on the film.

‡ Film thicknesses of $\sim 0.1 \mu\text{m}$ were monitored with a Kronos QM331 quartz crystal oscillator.

compared to porphyrins with lower triplet yields. An attempt to alter the lifetime of the porphyrin triplet by completely deuterating MgTPP, yielded the same results as the protonated form.

In the Wang cells, the power efficiencies varied from 1 to $10^{-4}\%$ for monochromatic light in the 400–450 nm region. The best results were obtained with magnesium tetraphenylporphyrin and cadmium porphyrin which yielded open circuit voltages of ~ 1 V, quantum yield of ~ 0.2 , and $\sim 1\%$ power efficiencies.

Fig. 3 Correlation between quantum yield and the first oxidation potential (versus SCE) of porphyrins in non-aqueous solvents. The line shown represents a least squares fit to the tetraphenylporphyrin data excluding PtTPP. (The latter is omitted because films of PtTPP on Al surfaces show unusually sharp absorption bands not observed on glass surfaces. A specific Pt-Al interaction may therefore account for the low quantum yield of PtTPP.)

The effects of film morphology, the use of mixtures of porphyrins, of other metals of low work function and of semiconductor electrodes are being investigated.

This work was performed under the auspices of the Chemical Sciences Division, US Department of Energy, Washington, D.C. under contract EY76-C-02-0016. We thank Drs A. D. Adler, C. K. Chang and L. D. Spaulding for gifts of porphyrins.

Spatial distribution studies of thermoluminescence using a high-gain image intensifier

Alan J. Walton

Open University, Oxford Research Unit, Foxcombe Hall, Boars Hill, Oxford, UK

N. C. Debenham

University of Oxford, Research Laboratory for Archaeology, 6 Keble Road, Oxford, UK

Thermoluminescence (TL)—the light emitted when a previously irradiated material is heated—is normally studied by heating the material under a photomultiplier (PM). This measures the total light emitted within the acceptance angle of the PM, but provides no information on the spatial distribution of the TL. The dating of archaeological specimens by means of their naturally acquired TL is a common application of this method. While such a spatially-averaging technique is acceptable in studying TL from homogeneous materials, problems can arise when it is applied to inhomogeneous materials, such as certain natural calcites¹, where TL emissions may be correlated with internal irradiation dose rates. As we shall demonstrate, a high-gain image intensifier (IIT) can be successfully used to investigate the spatial distribution of TL from such materials at light levels where even fast photographic emulsions fail to record any emission. So far as we are aware this is the first time that high-gain image intensification techniques have been used in such studies.

The equipment, shown in Fig. 1, is centred on an EMI type 9914 intensifier. This is a magnetically-focused four-stage tube (of phosphor-photocathode sandwich construction) with a bialkali input and a P11 output phosphor. At an EHT setting of 40 kV the light gain of the tube is around 10^6 . This is sufficient to ensure that approximately 65% of the photoelectrons leaving

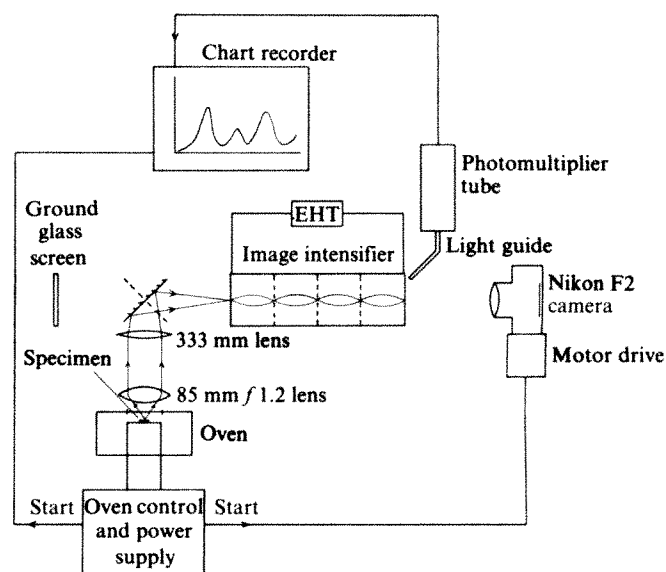

Fig. 1 Schematic diagram of the IIT and associated apparatus used to record the spatial distributions of TL emissions from a heated specimen in given temperature intervals together with the corresponding glow curve.

Fig. 2 Glow curves obtained from a sample of natural calcite obtained from a palaeolithic cave at Pont-Newydd, Wales. The specimen was heated linearly with time while a chart recorder traced the current from a photomultiplier tube which viewed the output phosphor of the IIT. Curve *a* shows the naturally acquired TL, and *b* the TL induced by an artificial γ irradiation of 12 krad.

the input photocathode (peak quantum efficiency 18%) are recorded as discrete 'points' on the film (Kodak Tri-X) taken in the camera viewing the output phosphor of the tube. (The camera is a motor-driven Nikon F2 with an *f*1.2 lens and a 4 dioptr achromatic doublet as a close-up lens.) The specimen is imaged onto the input photocathode using a microscope comprising a Canon 85 mm *f*1.2 photographic lens placed 'back-to-back' against a single-element lens of 333 mm focal

length, giving a linear magnification of 3.9. A rotating mirror allows the specimen to be brought into focus on either a ground glass viewing screen or the input photocathode. The advantages of such a microscope over a conventional one are the high aperture realised at low magnifications and the long working distance between the specimen and the 'objective' lens. The latter feature is important since the specimen is heated in an oven containing a 5-mm thick Spectrosil window and a 5-mm Chance-Pilkington HA-3 IR absorbing filter. The oven consists of an electrically-heated nichrome plate whose temperature, recorded by means of a NiCr/NiAl thermocouple, can be increased linearly with time². Starting the temperature ramp activates both the camera's motor drive and the time base of a chart recorder. The ordinate of the chart record shows the anode current of a PM viewing uniformly the total area of the output phosphor of the IIT; the resulting graph is conventionally called a glow curve.

In these studies we have used the intensifier system to observe the light emission from naturally occurring calcite of late Pleistocene age. Preliminary attempts to record even saturated TL in calcite using 3000 ASA film at 1:1 magnification had proved unsuccessful. Specimens were prepared in the form of 500 μ m thick slices. The surfaces were etched for 1 min in 1% acetic acid to eliminate spurious emission induced by the cutting of the slices³. Each specimen was first heated to observe its naturally acquired TL. The drained specimen was then given a γ irradiation of 12 krad and the artificially induced TL was observed in a second heating. Figure 2 shows the resulting glow curves for a sample of calcite (~10 mm across) obtained from a palaeolithic cave near Pont-Newydd in Wales. (The material from which the sample was prepared is stalagmitic, containing 1% of detritus, insoluble in HCl. Its mean ²³⁸U concentration is 0.5 p.p.m.) Figure 2*a* shows the natural TL and Fig. 2*b* the artificial TL. The

Fig. 3 Photographs of the output phosphor of the IIT showing spatial distributions of TL emissions from a specimen of natural calcite approximately 10 mm across on two subsequent heatings. Sequences *a* and *b* were taken concurrently with the respective glow curves *a* and *b* shown in Fig. 2. That is, *a* records the naturally acquired TL of the specimen, and *b* an artificially induced TL. Each frame was exposed for 10 s, and correspond to temperature intervals of 25 °C. (Frames in the sequence of natural TL below 200 °C are not reproduced as they recorded no light emission.) The 85-mm microscope lens was stopped at *f*1.2, and the Nikon camera lens at *f*1.2. The images recorded on the 35 mm Kodak Tri-X film were given standard development for a γ of 0.7 in Promicrol developer. All frames were given the same printing exposure. Photographs in *c* were taken at the end of each sequence of the cooled specimen under low-level illumination: a blue filter was used at the input end to enhance contrast. For these exposures both the microscope and camera lenses were stopped down to *f*5.6. Scale bar, 10 mm.

Fig. 4 Reproduction of the frame in sequence *a* of Fig. 3 corresponding to the temperature interval 275–300 °C, showing in more detail the intense ‘spots’ of TL emission against a more uniform, though banded, background. Scale bar, 1 mm.

corresponding sequence of photographs are shown in Fig. 3*a* and *b*. The temperature ramp rate was 2.5 °C per s and each frame was exposed for 10 s. Thus each frame records the integrated light emission within a 25 °C interval. Figure 3*c* shows the specimen photographed through the IIT under a low level of reflected light. (This procedure was adopted as conventional photomicrographs fail to reproduce geometrical distortions introduced by the IIT.) The glow curves shown in Fig. 2 are typical of those obtained by conventional PM techniques for many natural calcites. The peak at around 270 °C is commonly used in TL dating studies.

A striking feature of the sequences of photographs shown in Fig. 3 is the degree of non-uniformity in the light emission from both the natural and the artificial TL. (Frames in the sequence of natural TL below 200 °C are not reproduced as they recorded no light emission.) Looking at the sequence of natural TL emission (Fig. 3*a*) we see that most of the light emitted at the glow curve peak near 270 °C (Fig. 2*a*) in fact comes from localised ‘spots’ situated mainly in the lower half of the specimen. These spots may be seen more clearly in Fig. 4 which reproduces on a larger scale, the natural TL emission in the interval 275–300 °C. Their diameter is less than 0.5 mm and they appear against a more uniform emission. The glow curve of the artificial TL emission (Fig. 2*b*) shows a composite peak at around 125 °C in addition to the 270 °C peak. As can be seen from the sequence of photographs (Fig. 3*b*) the low-temperature emission is strongly banded with a few spots also contributing to the overall emission. Although the less intense emission at around 270 °C is more uniform it does show evidence of banding (particularly on the photographic negatives). The spots contribute a far smaller proportion of the high temperature emission in the artificial than in the natural TL. However, there is also evidence in the negatives of banding in the natural TL. Note that the growth layers visible in Fig. 3*c* are parallel to the banding seen in Fig. 3*a* and *b*. The bright background seen in the last two frames (375–400 °C, 400–425 °C) of each sequence is due to black-body emission from the heater plate.

There are at least two ready explanations for the ‘spots’ evident in the natural TL emission (Fig. 3*a*). The most likely one

is that they are associated with the detrital inclusions, insoluble in dilute HCl, which are present as 1% of the material. These mineral inclusions would be of geological age and likely to contain relatively high concentrations of uranium. Another possibility is that the spot emission originates from particles of limestone within the calcite matrix, the intensity of emission being mainly the result of their geological age. The apparent range of spot sizes (Fig. 4) is due to the varying depths of the emitting centres within the slice and the resulting variations in scatter of the emerging light. Observations on calcite samples from another site (Caune de l’Arago, France) have broadly confirmed the two basic features of spots and banding; the former being the predominant source of TL in young samples, the latter the predominant source in old samples (>200,000 yr). Adopting the methods of Fremlin and Srirath⁴ we have made fission-track maps of the old-age material and from these initial observations we have found that the uranium tends to be concentrated in the growth layers rich in iron impurities. These same impurity bands are also found to have higher optical attenuation coefficients. In addition the material’s TL sensitivity to irradiation is believed to vary between the different growth layers. It is a combination of these three effects which produces the banding structure which we have observed in the natural TL, while the last two factors are relevant in the case of artificial TL. Further studies are in progress on the spatial distributions of the TL and uranium in calcite with the ultimate aim of improving the reliability and accuracy of TL dates. Although still at an early stage, image intensification techniques already seem to provide a powerful tool for the study of TL in inhomogeneous materials.

We thank Dr M. Aitken for suggesting that calcite be used in these studies, Dr S. Green and the National Museum of Wales for supplying samples, Professor H. Hopkins for advice in the design of the microscope and David Lusty for constructing the microscope. This work was supported by the SRC.

Surface potentials of ice and thunderstorm charge separation

J. M. Caranti* & A. J. Illingworth

Department of Pure and Applied Physics, UMIST, Manchester M60 1QD, UK

There is no general agreement on the nature of the mechanism which causes thunderstorms to become electrified^{1,2}. Many scientists believe that charge is transferred when ice crystals collide with hailstones, and that subsequent gravitational separation results in field growth to breakdown magnitudes. Buser and Aufdermaur³ have proposed that the charging results from differences in the surface potential of ice. The measurements described here suggest that the surface potential of polycrystalline ice, such as would occur in a thunderstorm, is related simply to its past growth history. The sudden step in potential postulated by Buser and Aufdermaur as the ice surface changes from an evaporating to a growing state could not be detected. However, a natural hailstone grows by riming as it collects supercooled droplets, and these new measurements suggest that this effect results in much larger changes in surface potential.

* Permanent address: IMAF, Laprida 854, 5000 Cordoba, Argentina.

Fig. 1 Variation of the surface potential, V , of ice using gold electrodes with air temperature, T . The maximum potential always coincided with the ice temperature which was -8°C in this example; to the left the potential falls (ice cooler than air and condensing) and to the right it also falls as the warmer ice is evaporating.

Laboratory experiments which attempt to measure the charge separated when an ice crystal collides with a simulated hailstone, have not yielded consistent or predictable results. Possible clarification of this confusion is provided by Buser and Aufdermaur who found that when an ice crystal collided with various metal surfaces at -45°C the charge separated was proportional to the difference in the work function of the substances. Ice impacting on ice gave more variable results but if the target was evaporating it acquired negative charge whereas after deposition positive charge was favoured and the difference in charge per collision was equivalent to a change in the surface potential of the order of 0.2 V. This agreed with Takahashi's⁴ measurements of changes in the apparent surface potential of a copper electrode when ice was condensing on it or evaporating from it, and changes in the surface potential of a single crystal of ice also growing by deposition or evaporating at -10°C (ref. 5). The implicit assumption being that the surface potential change occurs in a single step. However, Buser and Aufdermaur concluded that the surface potential can be modified by so many factors that it may be difficult to predict in natural situations.

We report measurements of changes in the surface potential of ice made using a vibrating capacitor technique similar to that of Takahashi⁵. A cylinder of polycrystalline ice 10 mm thick and 50 mm diameter formed from distilled water was attached to the lower noble metal electrode by heating the electrode to near 0°C and warming the surface of the ice with hot air. The lower electrode was mounted on a Peltier element so that the specimen could be warmer or cooler than the ambient air. The upper electrode was made of gold plated gauze to allow an equilibrium vapour flux to the surface; if a solid electrode was used the results were variable and dependent on ventilation.

Figure 1 shows the uniform change in surface potential of about $1.5\text{ mV}^\circ\text{C}^{-1}$ as the temperature of the air was varied whilst keeping the ice and metal substrate at a constant temperature. The change in the surface as it evaporated or grew by deposition was clearly visible to the eye, but was not associated with any sudden change in potential. The upper electrode was always kept 1°C warmer than the lower one to prevent frost deposit. Without this precaution potential changes showing hysteresis similar to those of Takahashi⁵ were obtained as frost formed on the gauze and then evaporated.

Similar results to Fig. 1 were obtained for different ice specimens at different temperatures and dew points and for electrodes of Au, Pt, or Pd. Changing the lower electrode altered the voltage offset but not the shape of the curves. The measurements were reversible with no hysteresis. We confirmed Hobb's⁶ statement that copper-ice electrodes give results which are unpredictable and not reproducible, but we could produce results comparable with Takahashi's⁴ if we prepared the copper electrodes in the exact manner he describes.

The most striking changes in surface potential were observed when the ice surface was rimed with supercooled droplets from an ultrasonic generator (radius $50\text{ }\mu\text{m}$, water content $1\text{--}2\text{ g m}^{-3}$) falling at terminal velocity. Figure 2 shows that the change in surface potential was a function of temperature. The ice, air and supercooled water droplets were all at the same temperature; although a subsidiary experiment showed that if the ice was a few degrees warmer than the air the same results were obtained. Identical results were obtained with $10\text{-}\mu\text{m}$ radius droplets.

If the ice was only partially covered with frozen droplets a smaller change was observed, but when further layers were added to an already complete layer no further increase in potential resulted. The potential change was reversible. If the rime on the surface of the ice was melted and then allowed to refreeze slowly, the potential returned to its original value. As soon as the melted surface was refrozen the process could be repeated with a new layer of droplets. The slow refreezing of the surface was achieved by heating the upper electrode while it was close to the ice. If a very thin surface layer of water was rapidly frozen by exposing it suddenly to a stream of cold air the same change was observed as with riming.

The changes in potential could be very persistent. If the rime was left for 24 h the potential was practically unchanged and surface melting returned it to the previous day's value. Care was taken not to confine the ice specimen mechanically around its perimeter, otherwise slow and unpredictable changes occurred as the temperature varied. This is probably due to the stress within the ice⁷. If the rimed surface of the ice was exposed to an electrical field of 500 kV m^{-1} , or a charged probe touched the surface, the potential returned to its previous value a few seconds after the field was removed.

The effect of impurities was found to be small: 10^{-4} M solutions of NaCl, NH_4OH , and HF gave the same results as Fig. 2 and rainwater gave values within 20%. These changes persisted for many hours. When the concentrations were increased 100-fold, changes were more variable and the voltage decay took only several minutes. These higher concentrations are quite unrepresentative of atmospheric conditions.

Note that during the actual freezing of the droplets of both distilled and doped water large transient potentials are developed which we interpret as Workman-Reynolds freezing potentials⁸. Because the chance of an ice crystal impacting on a hailstone at a position where a supercooled droplet is in the process of freezing is so small, these freezing potentials are not likely to be important in thunderstorms.

Previous measurements^{5,9,10} of changes in potential during riming showed a steady change in potential proportional to the riming rate, and it was postulated that charged splinters were ejected, but it is now established¹¹ that the splinter production was caused by the high concentration of CO_2 used for cooling.

The origin of this potential change during the rapid freezing of supercooled water is a formidable theoretical problem. The

Fig. 2 Change in the surface potential, V , of ice after riming as a function of temperature, T . The unrimed ice surface is assigned a potential of 0V.

temperature dependence in Fig. 2 and the fact that rapid freezing of a very thin layer of surface water gives identical results, suggest that the rate of freezing is a controlling parameter. The freezing velocity of ice in supercooled water varies with the square of the degree of supercooling¹² which is similar in form to the first part of Fig. 2.

When ice is subject to thermal stress so that cracks appear, potentials up to 40V have been measured⁷ which decay rapidly and in a temperature dependent manner. The potentials developed in these experiments resulting from the rapid freezing of supercooled water were two orders of magnitude less and only decayed rapidly if the ice was heavily doped or subject to external stress.

The large differences in surface potential between a rimed and a non-rimed ice particle should be a more powerful mechanism for separating charge when ice crystals collide with hailstones in thunderstorms than the much smaller potentials existing between evaporating and condensing ice surfaces.

Allophane isolated from a podsol developed on a non-vitric parent material

A. W. Young, A. S. Campbell & T. W. Walker

Soil Science Department, Lincoln College, Canterbury, New Zealand

The relationship between allophane, an X-ray amorphous, short-range ordered aluminosilicate gel, found in soils derived from volcanic ash (Andosols) and the poorly ordered clay minerals present in the subsoils of podsoles (Spodosols) developed on non-vitric parent materials is uncertain. The similarity of many of the physical and chemical properties of these soils has led to postulations that 'allophane-like' materials also occur in podsoles^{1–4}. The high chemical reactivity of allophane and its intimate association with both soil organic matter and crystalline phyllosilicates and oxides has meant that earlier studies have involved either the examination of mixed crystalline–microcrystalline clay systems, or the use of dispersing reagents that would have caused at least the partial solution of any poorly ordered phases present. The established instrumental techniques of differential thermal analysis and IR absorption spectroscopy may be used to characterise allophanic materials, but only when they constitute virtually the whole of the clay fraction⁵. The present study characterises an allophane sample successfully isolated from a podsol profile.

The close similarity of the properties of naturally occurring soil allophanes and synthetic aluminosilicate gels^{6,7} suggests that the former are likely to have formed by precipitation from solution. If such a solution mechanism is involved, a vitric parent material should not be an essential requirement for allophane formation. The dominance of vitric parent materials in studies

involving soil allophanes, and the comparative paucity of convincing observation of allophane derivation from other parent materials⁸, may simply reflect the difficulties involved in isolating and characterising allophane when it constitutes only a small part of a clay fraction.

An opportunity to isolate and hence characterise a poorly ordered aluminosilicate gel formed during the genesis of a podsol has arisen during the study of a catena of podsolised yellow-brown earth soils on Bealey Spur, in the eastern foothills of the Southern Alps, North Canterbury, South Island, New Zealand (43°02' south latitude, 171°37' east longitude). The parent materials of the soils are mixed colluvium and locally derived loess overlying glacial till. The parent materials are all derived from rocks of the Canterbury Suite⁹. The dominant lithotype in the suite is a thick-bedded sandstone of Upper Triassic age. There are smaller occurrences of siltstones, mudstones, conglomerate, stratiform volcanics (basalts and dolerites), limestone and banded chert. The soils have developed under a forest vegetation of mountain beech (*Nothofagus cliffortioides* var. *solandri*).

Table 1 Chemical properties of the clay-sized separates of a podsol and selected allophanes

Size fraction (µm)	Podsol		Taupo B Taupo C	
	<0.2	0.2–2	<0.2	<0.2
Ignition loss 105–600 °C (%)	47.3	43.6	43.9	27.7
Organic carbon (%)	15.3	14.2	13.2	6.3
Total Si (%)	13.9	16.7	17.5	21.6
Total Al (%)	32.4	28.1	25.4	21.7

OH [−] released in 25 min by 0.85 M NaF at pH 6.8 (mmol g ^{−1})	39.8	32.9	23.9	22.2

Results are expressed on an ignited mass basis except for ignition loss and organic carbon which are on an oven-dry basis.

X-ray and microscopic examination of the sand fractions of the catena soils show them to be composed largely of quartz, altered feldspars and rock fragments consisting of quartz particles in a strongly weathered matrix. Minor to trace amounts of muscovite, biotite, chlorite, hornblende and garnet occur, particularly in the less weathered lower horizons. No fragments of volcanic glass could be detected.

The only minerals that could be determined in the silt fractions of the catena soils were quartz, feldspar, mica and chlorite. The clay fractions were dominated by phyllosilicate minerals derived from mica and contained minor amounts of gibbsite, kaolinite, allophane and quartz. Thermal and selective dissolution analyses indicated that allophane occurred widely throughout the catena. The greatest amounts of allophane and of gibbsite occurred in the lower part of the B horizons.

In the toeslope position of the catena the loess and colluvium were underlain by sand and gravel-sized sediments of similar mineralogical composition. These were thickly coated with a gel material. The advantage of the toeslope position is that translocation of the gel into an horizon that is essentially free of other clay-sized components has facilitated its isolation.

Fine ($<0.2\ \mu\text{m}$) and coarse ($0.2\text{--}2\ \mu\text{m}$) clay fractions of water-dispersed gel were separated by sedimentation and analysed by a range of instrumental and chemical techniques. In Table 1, and in Figs 1 and 2 the results are compared with data obtained from allophane isolated by water dispersion from the B and C horizons of a vitric Andosol, the Taupo sandy silt, from the Taupo Volcanic Zone of the central North Island¹⁰, and with that given by a synthetic aluminosilicate gel⁶ containing 60% by mass of Al_2O_3 .

Examination of the fine and coarse clay separates from the podsol by X-ray diffraction established their poorly ordered nature. X-ray diffraction patterns showed a broad hump in the baseline extending from 2.5 to 5.0 Å. The coarse clay fraction alone gave a weak diffraction peak at 3.35 Å which indicated the presence of a small amount of quartz. No evidence for the presence of cristobalite, feldspar, gibbsite, imogolite or phyllosilicates could be obtained from this technique or from thermal analysis, transmission electron microscopy or IR spectroscopy.

The IR spectra obtained from the podsol separates closely resemble that obtained from the synthetic gel (Fig. 1). Absorption maxima at 980, 550 and 350 cm^{-1} reflect a very low degree of silica polymerisation, and a corresponding dominance of Al—O , AlOOH and Al—O—Si bonds. The distinct shoulder at 1,080 cm^{-1} in the coarse clay spectrum indicates the presence of a silica-rich component in that fraction, but the absence of absorption at 800 cm^{-1} argues against the presence of appreciable amounts of discrete silica. The Taupo allophanes on the other hand have been shown to be mixtures of a highly aluminous gel phase similar to that found in the podsol or prepared synthetically, and a more siliceous comminuted volcanic glass phase¹⁰.

Molar $\text{SiO}_2/\text{Al}_2\text{O}_3$ ratios, based on total elemental composition, are lower for the podsol gels than for the Taupo allophanes (Table 1). As the latter are known to be mixtures of a gel phase and a comminuted glass phase, selective dissolution of the gel was attempted using both acid ammonium oxalate and sodium hydroxide as extractants^{11,12}. Both reagents extracted an alu-

minium-rich component. Unpublished data obtained in this laboratory have shown oxalate to be more specific than sodium hydroxide as an extractant of poorly ordered aluminosilicate gels in the appropriate experimental conditions. The $\text{SiO}_2/\text{Al}_2\text{O}_3$ mole ratios of the oxalate-extracted phases from both the podsol and Taupo samples are about half of the value of 1.0 commonly cited for allophanes¹³. Note that the reactive gels from the Taupo clays are more aluminous than those from the podsol, but hydroxyl release by fluoride⁵ indicates that the podsol contains the greater amount of allophanic material. The considerably higher $\text{SiO}_2/\text{Al}_2\text{O}_3$ mole ratios of the material extracted by sodium hydroxide from the podsol coarse clay and both Taupo clays indicates that this reagent has also partially dissolved the more siliceous phases known to be present in these samples.

The thermal characteristics of the fine and coarse clay from the podsol are almost identical to those of the Taupo allophanes and the synthetic gel (Fig. 2). All meet the defined requirements for allophane¹⁴. In addition, the effects of particle size, organic matter and carbon on the high temperature exotherm given by the podsol gels are consistent with those shown by allophane^{10,15}.

Fieldes has postulated that co-precipitation of weathering products in the subsoil of podsoles could lead to the formation of allophane¹⁶. Clearly, from the data presented here, the poorly ordered gel isolated from a podsol meets the widely accepted criteria for allophane. We have therefore confirmed that the genesis and persistence of allophane in podsoles is possible, and that its genesis does not require the presence of a poorly ordered parent material.

Gyromagnetism and the remanence acquired by a rotating rock in an alternating field

Alan Stephenson

Institute of Lunar and Planetary Sciences, School of Physics,
University of Newcastle, Newcastle upon Tyne NE1 7RU, UK

Although alternating field (a.f.) demagnetisation is routinely used in palaeomagnetism it has relatively recently been recognised that rotation of rock samples in the presence of an a.f. may introduce unwanted components of magnetisation. Doell and Cox¹ observed such magnetisations in 1967 but the phenomenon was not attributed to the effect of rotation until Wilson and Lomax² performed experiments about a single rotation axis and demonstrated the remarkable result that when an alternating field was applied at right angles to the axis of slow rotation, a remanent magnetisation was left antiparallel to the rotation vector after the a.f. had been smoothly reduced to zero. This magnetisation has been termed rotational remanent magnetisation (RRM). One of the explanations considered in attempts to account for the effect is that it is gyroscopic in origin, but order of magnitude calculations based on the rotation rate of the rock have indicated that such effects are insignificantly small^{2,3}, especially as RRM is detectable at rotation rates as low as 0.02 revolutions per second (r.p.s.). It is reported here that if appropriate assumptions are made regarding the magnetic behaviour of the rock, gyroscopic effects may be large enough to explain RRM.

When a rock is rotated at an angular frequency ω in a zero field, any magnetic moments within it will incline towards the rotation axis and a magnetic moment will appear antiparallel to the rotation vector. This is known as the Barnett effect and is a consequence of the intrinsic gyroscopic properties of the uncompensated electron spins which give rise to the moment of each magnetic particle. If the rock is static, the equivalent axial field B required to produce the same inclination of the moments towards the rotation axis is given by $\omega m/e$ where e/m is the ratio of charge to mass for the electron and where the magnetic properties of the particles within the rock are assumed to be due to electron spin rather than orbital motion. This equivalent field acts antiparallel to the rotation vector and is of magnitude $f_r \times 3.6 \times 10^{-11}$ T where f_r is the rotation frequency in revolutions per second (r.p.s.). For rotation rates of even several hundred r.p.s. it is thus insignificant compared to the fields required to produce a measurable remanence.

When, however, the rock sample is rotated in an alternating field, the changes in magnetisation which the rock experiences may be illustrated by Fig. 1, where for simplicity of explanation the alternating field has been represented by a series of moderately sharp pulses of alternate sign. Instead of considering

an anticlockwise rock rotation, Fig. 1 has been drawn with the rock stationary and the field axis rotating clockwise around it. A simplified explanation of the magnetisation changes in Fig. 1b are as follows. During the first pulse an isothermal remanent magnetisation (IRM) is acquired by the rock in position 1. Because the field axis is slowly rotating, the second pulse arrives at position 2 and as it builds up to its maximum value, it gradually removes the IRM acquired in position 1, modifying it by first flipping the low coercivity part anticlockwise towards the new direction but still exerting a torque on the high coercivity part which remains. This too is finally removed when the field reaches its maximum. During this build up of the second pulse, a positive (accelerating) torque (that is, in the same sense as the actual rock rotation) acts on the rock in Fig. 1b, c and d which are drawn for the rotation frequency (ω) less than the a.f. frequency (Ω). In Fig. 1e, however, where ω exceeds Ω , the torque is negative (decelerating) and the flip of the magnetisation is clockwise. This process is repeated in succeeding cycles.

During each flip, the rotation rate of the magnetic moments within the rock might be expected to be of the order of the reciprocal of the switching time or time constant (τ_t) of the flip. This may well depend on the coercivity of the particle but might be expected from a consideration of spin dynamics⁴ to be of the order of less than 10^{-8} – 10^{-7} s that is, the rotation rate of the magnetic moments during the flip will be of the order of 3×10^7 r.p.s. or greater. If the rock is stationary, as many moments will flip clockwise as anticlockwise and the system has perfect symmetry. Once rotation occurs, however, an asymmetry in the numbers of moments flipping in a particular sense is introduced and a corresponding torque will also be present as described above. The effective axial field B_r , which can be considered to deflect each moment towards the rotation axis as it flips towards the field direction, will thus be at least some 3×10^7 times greater than the value of 3.6×10^{-11} T quoted above, that is, about 1 mT or greater. This effective field is not a real field any more than is the anisotropy field, for example, but like the latter it is a useful concept. It is of the order of $\pi m/e\tau_t$ and will act in a direction antiparallel to the rotation vector describing the flip. For $\omega < \Omega$

Fig. 1 a, a.f., for simplicity represented by a series of pulses. b, Direction of the first two field pulses as the field axis rotates clockwise around the cylindrical rock sample at a low rotation frequency (ω): c, when ω is half the a.f. frequency (Ω); d, when ω is just less than Ω ; e, when ω is just greater than Ω .

Fig. 2 The dependence of torque and RRM on rotation frequency for a peak a.f. of 51 mT for igneous sample WD34.

the flip is anticlockwise in Fig. 1, that is, in the same sense as the actual rotation of the rock, and thus the effective field is antiparallel to the rotation vector (that is, negative). When $\omega > \Omega$, however, the flip is clockwise and the effective field is thus positive. A transient effective axial field of the order of 1 mT acting just when the particle moments are flipping might be expected to produce a similar axial magnetisation to a constant field of 1 mT acting in the presence of the same transverse a.f. with no rock rotation if the sense of the flip were the same for all moments.

This discussion is clearly greatly simplified as the motion of each moment during the irreversible flip will presumably be that of damped precession⁵ under the influence of the external field and the anisotropy field, the latter reversing sign when the moment crosses the energy barrier separating the two equilibrium positions (for uniaxial anisotropy). To avoid an analysis of this complex motion the approach used above is an attempt to simplify the problem by considering the overall bias which is likely to be imparted to the motion of the particle moments (as a result of gyroscopic effects) as they are forced to flip by the external field. This bias is then interpreted as being due to an equivalent field B_e and the remanence which results from the action of this equivalent field is considered to be similar to an anhysteretic remanent magnetisation (ARM) acquired in a constant field in the presence of the much larger peak a.f. RRM is thus interpreted (like ARM) as being due to a statistical partial alignment of moments caused by a biasing field (B_e) in the presence of a much larger a.f. Because the moments do not all flip in the same sense, however, (the role of rotation is to introduce a bias favouring one particular sense of flip), the maximum RRM observed might be expected to be rather less than the ARM acquired in 1 mT in the conditions described above. The sign of RRM from this analysis is in agreement with the results of Stephenson³ who investigated RRM up to rotation speeds of 60 r.p.s.

To investigate RRM at higher rotation speeds, measurements were made on two igneous samples which were rotated at frequencies between 1.5 and 275 r.p.s. in a peak alternating field of 51 mT (ref. 5). This range of speeds was achieved by using a turbine driven from a compressed-air supply, with the rock sample mounted in the rotor. The magnetic torque exerted by the alternating field was measured by observing the initial rate of change of angular momentum imparted to the sample plus rotor when the field was suddenly applied to the stably spinning rotor⁶. The RRM was given to the sample by spinning the sample at the desired speed, applying the a.f. by quickly turning up the current in a surrounding coil by means of a Variac, and then after a second or two, smoothly reducing the current to zero over a few seconds.

Figure 2 shows the RRM and torque results for one of the samples coded WD34. In accordance with the above explanation, RRM is negative (except between 12 and 40 r.p.s.) for $\omega < \Omega$, and positive for $\omega > \Omega$. The fact that neither RRM nor torque exhibit further sign changes at higher rotation rates,

which might be expected from the simple explanation, because the a.f. is not, in fact, a series of pulses acquired during the decreasing part of the cycle is over a range of angles so that the torque is then always (retarding). A two dimensional numerical model based on single domain particles and a coercivity determined from the acquisition of IRM as a function of applied field has enabled a torque curve to be computed which is very similar to the above experimental result⁵.

The above description is greatly simplified, and, while the numerical model is more sophisticated than this, it is by no means a complete magnetic description of the rock, and therefore the unexplained experimental observation of the secondary sign change between 12 and 40 r.p.s. is possibly due to deficiencies in the model rather than because the above explanation is necessarily at fault. This secondary sign change was not so marked in the other sample and did not occur in the two samples investigated by Stephenson³.

The direct field required to produce an ARM of the same magnitude as the maximum RRM observed was about 100 and 20 μ T for the two samples (in a peak field of 136 mT rather than 51 mT). The estimated 1 mT transient effective field, which is thus a consequence of the sudden flip of the moments, which occurs when the field strength and direction becomes favourable would thus seem to be easily strong enough to account for the phenomenon of RRM. Moreover, this mechanism does not depend on the absolute rotation rate of the rock but only on the rotation of the field relative to the rock. This is in agreement with experimental results of Stephenson who found that it is immaterial whether the rock rotates or whether the a.f. axis rotates about the stationary sample³.

Perhaps RRM may thus be an example of a new type of remanence for which the name 'gyroremanent magnetisation' or GRM might seem to be appropriate.

A gyroremanent magnetisation in anisotropic magnetic material

Alan Stephenson

Institute of Lunar and Planetary Sciences, School of Physics, University of Newcastle, Newcastle upon Tyne NE1 7RU, UK

An effect whereby an anisotropic magnetic material acquires a remanence on exposure to an alternating magnetic field (a.f.) is predicted from an analysis of the phenomenon of rotational remanent magnetisation (RRM). The remanence, which is of gyromagnetic origin, is produced even when there is no relative rotation between sample and field and all constant fields have been eliminated. The effect is demonstrated in magnetic recording tape and, as well as having important implications for a.f. demagnetisation techniques, may be relevant to magnetic recording processes.

The phenomenon of gyromagnetism is well known (see ref. 1 for a review) but it has not generally been considered that it could ever produce an easily measurable remanent magnetisation. It has recently been suggested, however^{2,3}, that the RRM identified by Wilson and Lomax in rock samples⁴, can be explained in terms of a gyromagnetic effect associated with a predominant sense of flip of the moments inside the sample as it

located in an alternating field. In a simplified approach to the complex problem of determining the motion of the particle moments during the flips, it has been suggested that, because of the sudden enforced rapid rotation of their associated angular momentum vectors, the particle moments can be considered to be deflected towards the rotation axis by a transient field B_g of the order of $\pi m_e / e \tau_f$ (where e/m_e is the charge to mass ratio for the electron and τ_f is the time of flip of the moment). It is this effective transient axial field, acting during the flip, which produces the remanence, and therefore in any system where a particular sense of flip predominates, such a magnetisation should result. Thus a rotating field of constant amplitude should also produce a remanence antiparallel to the field rotation vector, provided that the field is strong enough to produce the irreversible flips of the moments. In such a case, the resultant magnetisation should be independent of the rotation frequency f , provided that $1/f \gg \tau_f$. Of even greater interest, however, is that this approach leads to the prediction that rotation, either of the magnetic material or the magnetic field, is not a necessary condition for gyromagnetic effects to produce a remanence. This remanence, here termed a gyromagnetic remanent magnetisation (GRM), is likely to be produced whenever there is an asymmetry in the number of moments which flip in a particular sense.

Consider a uniaxial single domain particle orientated at an angle θ to an alternating field (see Fig. 1). Successive pulses of a weak a.f. merely cause reversible excursions of the moment away from the easy axis but a stronger field will cause the moment m to flip between the two easy directions (actually between two positions which are governed by the anisotropy field and θ). If θ is positive as in Fig. 1a, the sense of the flip will always be clockwise. That is, the rotation vector describing the flip is in the negative z direction. If, however, θ is negative as in

Fig. 1 A diagram to show the sense of the irreversible flip of the moment of a single domain uniaxial particle when subjected to an alternating field with peak value comparable to the anisotropy field.

Fig. 1b, the flip will be anticlockwise. As a result of the flip and because of the intrinsic gyroscopic behaviour of the moment of the particle, the moment will be deflected towards the $+z$ direction in Fig. 1a ($-z$ in Fig. 1b)^{2,3}. Clearly in the case under consideration, no remanence can be retained antiparallel to the flip vector because the moment will always lie along one of the two easy directions when the field is removed. In an assembly of particles, however, such as in a rock, where each particle has three unequal orthogonal axes representing its anisotropy, and where there are many different particle orientations, any inherent bias imparted to the overall motion of the moments of the assembly during the flips would be expected to produce statistically a remanent magnetisation in the opposite direction to the average flip vector in an exactly analogous way to that discussed previously in connection with RRM^{2,3}. In an anisotropic rock, therefore, with its easy magnetisation axis orientated along the x axis in Fig. 1 (making use of the same diagram), the bulk anisotropy will cause the isothermal remanence acquired in each pulse of the a.f. to be deflected towards the nearest easy direction, so that the same sense of flip as illustrated will predominate and an effective field antiparallel to the average flip vector will be present.

Fig. 2 Orientation of 100 layers of magnetic recording tape. The dashed line in the x - y plan indicates the a.f. axis for positive θ as in Fig. 1a.

This effective field will thus produce a GRM perpendicular to the a.f. and anisotropy axes. The direction (but not the magnitude) of the GRM will be given by the vector $\mathbf{A} \wedge \mathbf{F}$ where \mathbf{A} is a vector along the anisotropy axis. The field axis is specified by a vector \mathbf{F} , the direction of which is such that θ (the angle between \mathbf{A} and \mathbf{F}) always lies between $-\pi/2$ and $+\pi/2$. As the orientation of the field axis is thus altered through $\theta = 0$, the sign of the GRM should thus change, being negative (along the $-z$ direction) for $\theta < 0$, and positive for $\theta > 0$. The magnitude of the GRM might be expected to depend on θ , the flip time (τ_f) of the particle moments, and the magnitude of the anisotropy. For a very anisotropic sample, GRM might be expected to be of similar magnitude to the ARM acquired in a transverse a.f. of the same strength as that used to produce the GRM, and in the presence of a steady field of magnitude $\pi m_e / e \tau_f$.

To test this hypothesis an anisotropic sample was fabricated by stacking together 100 strips of magnetic recording tape (see Fig. 2). Each strip was of dimensions 18 mm \times 6 mm. The long axis of each strip (x axis) was mounted horizontally in a non-magnetic holder with the plane of each strip vertical (z axis).

Fig. 3 The dependence of the z axis magnetisation (which is a GRM) for 100 layers of magnetic tape when subjected to a 274 Hz alternating field of 50 mT peak at an angle θ as in Fig. 2.

Initial susceptibility measurements yielded values of 128 and $85 \times 10^{-6} \text{ m}^3 \text{ kg}^{-1}$ respectively (per unit mass of tape), in directions along and perpendicular to the plane of the strips. Because the distribution of the particles is essentially isotropic in the x - y plane⁵ these differences in susceptibility are due to the differences in demagnetisation factors in the two directions. Nevertheless this shape anisotropy should produce the same sense of flip as illustrated in Fig. 1 when the x direction coincides with the long axis of the tape.

The tape was demagnetised by tumbling the composite sample in an a.f. demagnetiser which reduced the remanence to a suitably low value. This was measured on a spinner fluxgate magnetometer used for measuring the remanence of rock samples. The sample was then orientated at various angles as in Fig. 2 inside a set of Helmholtz coils which cancelled the Earth's field. The a.f. was increased to a peak value of 50 mT (at 274 Hz) and then slowly decreased over a time of about 1 min and any resulting remanence was measured. Between each different orientation the sample was demagnetised by tumbling. A z -axis remanence did indeed result from this procedure and this is plotted as a function of θ in Fig. 3, where it is apparent that the GRM has the general form expected from the preceding analysis. This result should be independent of a.f. frequency f , provided that $1/f \gg \tau_r$.

When the pair of Helmholtz coils cancelling the Earth's vertical component was switched off and a field of $44 \mu\text{T}$ acted along the $-z$ direction, the magnetisation changed from 7 to $-21 \times 10^{-3} \text{ Am}^2 \text{ kg}^{-1}$ at $\theta = +60^\circ$. This suggests that an ARM of about $28 \times 10^{-3} \text{ Am}^2 \text{ kg}^{-1}$ is being added in opposition to the

GRM, so that the effective field producing the GRM, at least when the peak a.f. is 50 mT, is equivalent to a steady ARM field of about $11 \mu\text{T}$. This value is not unlike those estimated from RRM experiments on rocks^{2,3}.

The implications of this result are considerable for the a.f. demagnetisation of anisotropic rocks, since it implies that a single axis non-tumbling demagnetisation system will invariably introduce a GRM into the sample unless the anisotropy axes of each rock happen to be orientated at 0 or 90° to the a.f. axis. Such magnetisations in the past may well have been misinterpreted as ARM, but an orientation dependence check should indicate the presence of a GRM. Such a dependence is now under investigation in a rock sample and will be described at a later date. This effect may also turn out to be of importance in magnetic recording. It may also prove to be a useful tool in studying magnetisation rotation process in magnetic materials and anisotropy in rocks and minerals.

Of perhaps even greater interest, however, is that gyromagnetism can produce an easily observed remanence in magnetic materials even when they are merely exposed to an alternating field, and this would appear to be an effect which has hitherto been unsuspected.

A braidplain facies model for the Westphalian B Coal Measures of north-east England

R. S. Haszeldine & R. Anderton

Department of Applied Geology, University of Strathclyde, Glasgow G1 1XJ, UK

The Westphalian B (Coal Measure) sediments of Northumberland, Durham, and the other northern English coalfields were deposited on extensive coastal plains between several peripheral source areas and the Saint George's Land block to the south. We report here a facies model resulting from studies of fluvial sandstones in the Westphalian B of Northumberland and Durham and suggest that sandy braidplains were an important feature of the depositional environment in this coalfield. Braidplain sand sheets, and associated washouts in underlying coal seams, formed following tectonic uplift of local source areas supplying recycled sands. Parts of this model may be extended to other coalfields in northern Britain.

It has often been assumed that the Coal Measures environment was a large-scale delta top^{1,2}, with peat-forming swamps laterally equivalent to meandering rivers, and a marine influence becoming more important towards the central Pennine coalfields³. Detailed interpretations of parts of the Pennine coalfields have been made as the deposits of swamp, lake, lake delta and river channel environments^{4–6}, but no model to explain the major sedimentary features of this coalfield, or the differences between the different Pennine coalfields, has emerged.

In the Northumberland and Durham coalfield the Coal Measures can be divided into three main sedimentary facies associations. (1) The marine band facies consists of distinctive fossiliferous silty mudstones up to 2 m thick. These are interpreted as the deposits of occasional, low energy marine transgressions. (2) The coal-bearing facies consists of part or all of a sequence which, when complete, comprises black fossiliferous

shales, passing up into grey, finely laminated mudstones and siltstones and overlain by seat-earth and coal. These siltstones may also contain very fine-grained sandstones, forming sheets 10–50 cm thick, of limited lateral extent, and often containing bioturbation, climbing ripple or trough cross-lamination structures. This is the dominant facies association; it ranges from 10 cm to 15 m in thickness and is interpreted as the deposits of shallow lakes with small delta infills, capped by swamp vegetation. (3) The major fluvial facies comprises fine to very coarse sandstones 4–35 m thick, with no autochthonous coal. Each sandstone has an erosional base and fills any washouts in the underlying coal seam, so any understanding of these major sandstones and their associated washouts is of great economic importance to coal exploitation. The lower part of the sandstone is often conglomeratic, containing locally eroded clasts of ironstones and angular partially lithified silts, together with clasts of coalified once-leathery peats and fossilised log jams. The sequence passes up into trough and tabular cross-bedded sandstone in sets 1–3 m thick forming cosets 5–15 m thick with unimodal palaeocurrent vectors paralleling washout trends. These are followed by about 2 m of ripple-laminated siltstones and fine sandstones, and may be capped by seat-earth and coal of the coal facies. There is no evidence for any significant systematic lateral river migration. This type of sequence is interpreted as the deposits of a river in which a rapid, unidirectional flow decelerated, allowing silting of the channel and eventual blanketing by vegetation. Field and borehole data show that these sandstones form thin sheets, usually 10–15 m thick, but occasionally up to 35 m in thickness. These can cover large areas of the coalfield ($>1,500 \text{ km}^2$), but are not continuous, leaving occasional 'islands' of older sediments. These major stratigraphic and facies relations are quite unlike those of migrating and avulsing fluvial systems⁷ and we suggest that the vertical sequences are not due to the migration of laterally equivalent facies, but rather to major environmental changes with time. These sandstone sheets probably resulted from the periodic invasion of high-energy braided rivers eroding into and spreading over an otherwise low-energy coastal plain, to form large areas of sandy braidplain (Fig. 1). There were no major deltas. This implies periodic rejuvenation of the river system by changes in discharge or of slope, possibly originating from

tectonic, climatic or eustatic changes. Thus in any one seam, washouts were formed synchronously after river rejuvenation when the stream power was rapidly increased, but before erosion produced a significant sediment load. Consequently, many washouts are narrow, deep and of low sinuosity, but as the rivers lost power and aggraded vertically, they continued to widen, often by eroding along the tops of peat seams which formed underlying cohesive layers (Fig. 2). Because these major sandstone events were time horizons, they may be of value for seam correlation.

In Northumberland and Durham several braidplain sandstones fill washouts trending east/west, whereas only a few fill north/south washout trends. Palaeocurrents deduced from major bedforms and coincident washout trends may be directed eastwards or northeastwards in one sandstone, and be succeeded by westward-directed palaeocurrents and washouts in the next. This periodic palaeoslope reversal implies tectonic tilting from sandstone to sandstone. The palaeoslope reversal is also reflected in a difference in lithology between successive sandstones, suggesting different source areas. For example, a sub-rounded/rounded subarkose with orthoclase and minor muscovite may be succeeded by a sub-rounded subarkose with perthitic and microcline feldspars, and minor garnet. All of these features can best be explained by repeated tectonic uplift and erosion of local sedimentary source areas to the west, north and east, rather than by a single large river system depositing far-travelled detritus. Note that this province was probably tectonically active during the Westphalian^{13,14}. Thus it is possible that much of this mature, rounded, sandy detritus was reworked from easily eroded areas of Namurian or older sediments on the Southern Uplands, Mid North Sea High and North Pennines. Such source areas only a few tens of kilometres distant need only have been uplifted by a few tens of metres to have triggered off erosion and provided a slope sufficient to maintain braiding in sandy sediment, given a reasonable discharge variation^{10,15,16}. Away from the source areas river slope decreased. This caused a decrease in river power, deposition of the coarser

bedload, and a transition to meandering rivers further southwards (Fig. 1). After the source areas had been reduced by gullying, removing any stored sediment¹⁰, the braidplain would silt up, and the coal facies re-establish. Occasionally, some of the large braidplain events influenced the distal central Pennine areas, causing unusually widespread washouts and sands. The silts and very fine sands normally deposited on this coastal plain show evidence of river migrations and avulsions^{4,5}, however, these features were only well developed in the distal parts of the overall coastal plain.

Climatic change is unlikely as a cause of this river rejuvenation, as such a change would have had to have been repeated rapidly many times within the Westphalian B and would not explain such divergent palaeocurrents and source areas.

Worldwide eustatic sea-level changes are not favoured as the cause of river rejuvenation because of the palaeocurrent, petrographic and proximal to distal features mentioned above. During eustatically induced regressions^{8,9}, any fluvial transportation would be expected to reach across former shelf or coastal plain areas, and deposit sands in shoreline areas^{8,10,11}. While each regression continued, erosive gaps and a recurrent linear washout trend down the palaeoslope would be expected to have developed in these coastal shelf areas. However, the evidence above, together with borehole information from Northumberland and Durham, does not support this in the Westphalian B.

The idea that the Northumberland, Durham and probably Cumbrian coalfields were slightly elevated proximal areas with respect to the other Pennine coalfields is supported by regional marine band variations. These proximal coalfields have thinner marine bands containing a low diversity near-shoreline fauna and several bands were not deposited at all³. This suggests that the sea was unable to transgress into these proximal areas as often, or for as long a period, as elsewhere. The Mid-Westphalian A to Mid-B has very few marine bands and contains the most productive coal seams¹⁷. The prevailing regional subsidence may have been matched by clastic supply¹² during this

Fig. 1 Schematic palaeogeographical block diagram showing large-scale environmental changes in Coal Measures. Not drawn to scale, but a distance of several hundreds of kilometres from source areas to sea is envisaged. Plan shows proximal to distal changes proposed for: *a*, a period of maximum braidplain development, passing into coastal plain swamp. Source areas were uplifted. *b*, The coastal plain swamp encroached as the braidplain was abandoned. Source areas now eroded. Block section shows the extent of previous braidplains, but not detail of coal or marine facies.

Fig. 2 A schematic cross-section perpendicular to palaeocurrent flow shows the sequence of events resulting from river rejuvenation. Horizontal scale greatly shortened. *a*, Coastal plain coal facies, fed by small low energy avulsing and meandering rivers, which deposited predominantly fine-grained sediments and formed minor lake deltas within a swamp environment. *b*, Uplift of source area by only 10–20 m, not necessarily synchronous or of equal amount in all source areas, caused river rejuvenation. Rivers formed new channels along lines of least resistance through topographically low areas such as pre-existing rivers, or old lake basins. These rivers initially carried little coarse sediment and rapidly cut down into the older coastal plain sediments, forming low sinuosity washouts where peat was eroded. *c*, In areas proximal to source, the rivers quickly received coarse sediments and aggraded. They then rapidly widened along the top of the cohesive peat layers by bank collapse, forming basal conglomerates. Sand load continued to be deposited in proximal areas forming a braidplain, and usually only the fine sediments were carried down to distal coalfield areas, where washouts from the initial increased water discharge were filled with silts and fine sands. *d*, As the source area became rapidly eroded and aggradation continued, a near equilibrium base level was restored and rivers lost their power and silted up to form large shallow lakes. The distal coastal plain coal facies gradually encroached northwards and swamp conditions resumed with steady state graded rivers. If regional subsidence was too rapid, the sea transgressed, forming a marine band.

period. Conversely, in the Upper B, regional subsidence often outpaced supply, resulting in many marine transgressions. It seems likely that such transgressions had a significant tectonic and sedimentary control independent of eustatic sea-level changes. The large time range estimated for a goniatite zone fauna⁹ may be significant in the correlation of some apparently more widespread marine bands.

We thank the IGS and the NCB for borehole data and valuable discussions, and A. K. Barraclough, G. A. Blackburn and M. J. Russell for advice. R.S.H. is supported by a NERC grant.

Silurian or Upper Ordovician fossils at Guolasjav'ri Troms, Norway

R. E. Binns

Institute of Biology and Geology, University of Tromsø, PB 790, 9001 Tromsø, Norway*

R. A. Gayer

Department of Geology, University College, PO Box 78, Cardiff CF1 1XL, UK

In August 1979, specimens of rugose and tabulate corals, crinoids and brachiopods (Fig. 1*a*) were recovered from metalimestones in a belt extending 0–3.5 km north-west of Guolasjav'ri, a mountain lake south-east of Kåfjord, Troms, in Norway (Fig. 2, locality I). This is the first fauna to be recognised in this part of the Caledonian nappe sequence in Troms. The presence of corals proves that these metalimestones are not older than Middle Ordovician which imposes constraints on the correlation of this series with units in the Caledonides to the north and south and has an important bearing on the problematic relationship between the dominant Scandian phase (mid-Silurian¹) of the Central Scandinavian Caledonides and the Finnmarkian phase (late Cambrian²) of northernmost Scandinavia.

Padgett³ erected the first lithostratigraphy in this part of the Norwegian Caledonides (Fig. 3). Within his 2,600 m non-granitised Birtavarre Series, he named the unit in which the fauna has been found the Guolas Limestone Series. Where the fossils are preserved, this has undergone Barrovian-type, amphibolite-facies regional metamorphism synchronous with polyphasal deformation (our unpublished data). These fossils are therefore poorly preserved, although they remain surprisingly little deformed. The two least altered specimens are identified as halysitids with ordinary lacunae and elliptical corallites about

* Present address: Dybdahlsvn. 20, 7000 Trondheim, Norway.

Fig. 1 Photographs of the fossils. *a*, Crinoid ossicles and a fragment of a ribbed brachiopod at outcrop locality 1 (Fig. 2). Coin is 1.5 cm in diameter. *b*, Halysitid tabulate coral, cut surface; from locality 2 (Fig. 2). Scale bar, 0.5 cm.

1 mm wide in cross-section (Fig. 1b), indicating a Silurian or possibly late Ordovician age.

Although tectonic dislocations (for example, the Capps Thrust) were recognised³ within the Kåfjord sequence, the stratigraphy was not thought to have been disrupted significantly. Another thrust^{4,5}, however, below the lower quartzite and marble units, not recognised by Padget, forms an important regional nappe boundary (see for example, ref. 6 and Fig. 3). Recent field work (largely by R.E.B. to be detailed elsewhere), also supported by evidence farther afield, has demonstrated a simpler stratigraphy than that of Padget and other workers^{7,8}. The succession (Fig. 3), including horizons of intermediate or acid lavas in a 350–400 m thick basic pillow-lava accumulation near locality I, appears to be repeated by large-scale, sub-recumbent folds. Way-up evidence (mainly from pillow shape and the clast content of an immediately overlying polymict conglomerate) supports a normal stratigraphic order in the fossiliferous part of the sequence just north of Guolasjav'ri.

One of the outstanding problems of the Kåfjord sequence has been its correlation within the Scandinavian Caledonides. Zwaan and Roberts⁸, although recognising repetitions within Padget's³ Kåfjord stratigraphy, which they sought to explain entirely in terms of thrusting, correlated these rocks, in accord with the orthodox view^{2,9–11}, with the upper portion of the well documented Sørøy stratigraphy¹² (Fig. 2). The late Precambrian–late Cambrian age of the latter is based on an early to middle Cambrian archaeocyathid fauna¹³ and on radiometric age dating (see refs 2, 14). Quenardel's⁷ interpretation seems to be largely a combination of those of Padget³ and Zwaan and Roberts⁸. In contrast, some economic geologists¹⁵ postulated an Ordovician age for the ore-bearing rocks within the Kåfjord sequence on account of the similarity in ore paragenesis between these sulphide ores and some farther south in Scandinavia.

The lithostratigraphic correlation between the Kåfjord and Sørøy sequences led Sturt, Roberts and others^{2,7,8,11,16} to assume without reservation that the late Cambrian Finnmarkian orogenic phase extended through the Kåfjord area and much farther south into Nordland and adjacent parts of Sweden. They thus discounted the previous correlations^{17–20} between the southern part of the area and fossiliferous Ordovician–Silurian (Köli) rocks a little to the south. The discovery of a late Ordovi-

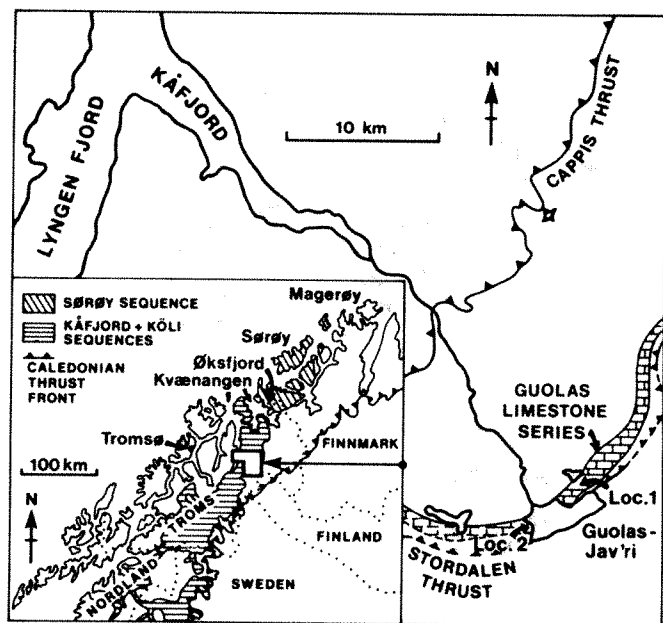

Fig. 2 Map of the Kåfjord region to show the fossiliferous localities in the outcrop of the Guolas Limestone Series. Inset shows location of the Kåfjord region within the outcrop of the Köli/Kåfjord/Sørøy sequences.

Fig. 3 The interpretation of the stratigraphy of the Kåfjord region according to Padget³ (right) and the revision proposed in this work (left). The column is not to scale—the sequence above the Stordalen Thrust (Padget's non-granitised Birtavarre Series) is ~2,600 m thick.

cian–Silurian fauna in the Kåfjord rocks which are shown to belong to a stratigraphic sequence only disturbed by tectonic duplications, makes the lithostratigraphic and tectonic correlations of this sequence with that of the Köli and Gasak nappes^{18,20} of central Nordland and adjacent parts of Sweden discussed by Binns⁶ more likely. Geochemical comparisons between the volcanic rocks of the Kåfjord and Köli sequences are under way and these may strengthen this correlation. Padget's Capps Thrust may define the nappe boundary but lithological and tectonic complications south-west of Kåfjord prevent this from being more than a tentative proposal at this stage.

Even an approximate chronostratigraphic correlation between the Kåfjord and Sørøy sequences can no longer be entertained. It seems possible to trace the Kåfjord sequence laterally through to the Kvaenangen–Øksfjord area^{3,4,8,9,23,24} (Fig. 2). At Øksfjord the strata are invaded by the syn-orogenic (Finnmarkian phase; climax 500–550 Myr ago²) Seiland Igneous Complex^{21,22}. If the lithostratigraphic correlation and the Sørøy region isotopic age evidence are to be relied on, it is difficult to explain the ensuing relationship without invoking rapid diachronous southward younging of the active orogenic belt and of regional sedimentation during late Precambrian–late Silurian time. Neither geophysical work²⁵, nor mapping^{9,21,24} have revealed a major transverse tectonic break between Øksfjord and Kvaenangen and tectonic interleaving of older and younger nappe units is incompatible with the correlation of Hooper and Gronow²³ and Armitage *et al.*⁹. Equally rapid tectono/thermal diachroneity has been recognised in Cenozoic triple plate junction migration²⁶ but sedimentation diachroneity of at least 100 Myr in a lateral distance of about 100–200 km (an estimate of pre-folding relationships) seems inconceivable. Hence we conclude that the correlations between Øksfjord and Kåfjord, and the Sørøy region isotopic age evidence require critical re-consideration. Perhaps the existence of an independent Finnmarkian Orogenic belt is in doubt.

We thank N. Aarhus, N-M. Hanken and E. Thomsen for advice on the fossils. N. Aarhus, N-M. Hanken and R. J. Humphreys for helpful comments. R.A.G. acknowledges the support of a Royal Society grant.

A new hominid fossil skull (L.H. 18) from the Ngaloba Beds, Laetoli, northern Tanzania

M. H. Day*, M. D. Leakey† & C. Magori*

* Anatomy Department, St Thomas's Hospital Medical School, London SE1 7EH, UK

† Olduvai Gorge, PO Box 30239, Nairobi, Kenya

In 1976, a fossil hominid skull was recovered from the Ngaloba Beds at Laetoli, Northern Tanzania; its morphology is discussed here. The discovery of this skull is of great interest and importance because of its very substantial presumed antiquity and its largely anatomically modern morphology. The discovery has considerable implications for the antiquity and origin of modern *Homo sapiens*, a subject of longstanding interest and one which has gained renewed attention recently.

The Ngaloba Beds¹, lying above the vogesite lavas which separate them from the underlying Ndolanya and Laetolil Beds^{2–4}, are stream deposits, principally sandstones and claystones, of which only patches are preserved. These patches consist chiefly of detritus eroded from the underlying Ndolanya and Laetolil Beds and they contain artefacts of Middle Stone Age affinity. The skull was recovered from a 2-m thickness of the Ngaloba Beds at Locality 2 that also yielded artefacts, some fossil reptilian and avian bones as well as fossil mammalian bones. This exposure is principally of sandy claystone and contains a water-worked vitric tuff. The tuff is trachytic and contains the pyroclastic minerals biotite and anorthoclase; it is tentatively correlated with the marker tuff in the lower unit of the Ndutu Beds at Olduvai Gorge⁵. This is the only trachytic tuff younger than Bed IV in Olduvai Gorge and its age is estimated at $120,000 \pm 30,000$ yr BP (R. L. Hay, personal communication). The skull was found by E. Kandini *in situ* but eroding out of the deposits.

The skull is almost complete and includes the bones of the vault, much of the base, both temporal bones, part of the

sphenoid and much of the face including the palate and part of the upper dentition. The bones are all heavily mineralised with no signs of pathology, but there are signs of post-mortem plastic deformation that has resulted in torsion to the right of the supraorbital region and some springing of the temporo-occipital suture on the left. As recovered, the skull was in 22 pieces and coated with greyish calcareous matrix. Cleaning produced fossil bone of an ivory colour and natural texture with the preservation of remarkable surface detail. It was possible to reassemble the vault and base into one structure and the paired maxillae into

Fig. 1 Left lateral view.

another. There is no point of contact between the facial skeleton and the calvaria although very little bone is missing. The relationship between these two main fragments of the skull remains speculative. The age at death seems to have been between 18 and 30 because the sutures of the vault are all open, but one third molar is present and fully in wear. The state of wear of this tooth suggests that the upper end of the age range is most likely.

Dimensions of the skull are given in Table 1. In lateral view (Fig. 1) the skull shows several striking features including marked recession of the forehead, a rounded occipital profile, an undercut central occipital torus and a small mastoid process. The frontal view (Fig. 2) shows a divided supraorbital torus, a relatively low vault and a mid-parietal swelling. The frontal bone is very slightly keeled in the sagittal plane but there are no

Fig. 2 Frontal view.

Table 1 Skull dimensions

Greatest length (glabella/opisthocranion)	—	205 mm
Greatest breadth (biparietal)	—	140 mm
Cranial index	—	68.3
Vault thickness (right and left parietomastoid and bregma)	—	12 mm

Fig. 3 Occipital view.

marked parasagittal flattenings. In occipital view (Fig. 3) the general frontal profile is confirmed but the parietal vault expansion is more clearly seen in the form of distinct parietal bossing or angulation.

The basal view (Fig. 4) of the skull shows plastic deformation which has affected the left frontal bone and to some extent the position of the left temporal bone. There are well marked frontal sinuses exposed by the loss of the ethmoids; the sinuses extend laterally into the orbital roof and posteriorly between the tables of the skull. The sphenoid is preserved in part and includes part of the body, greater wing and lesser wing of the right side and part of the body on the left. Both temporal bones are present and the right one is virtually complete. Both styloid processes are broken off but both the fossae for articulation of the mandible are present. The foramen magnum and its associated structures are entirely missing.

Both mastoid processes are limited by deeply incised mastoid notches (digastric grooves), and on the right there is a prominent occipitomastoid crest. The cranial capacity has been estimated by the water displacement of a cavity cast and the mean value of six estimates is 1,200 cm³ with a small range of observational error.

The facial fragment consists of the paired maxillary bones including the hard palate, the alveolar processes bearing some teeth as well as both zygomatic processes and the frontal process on the left. The dental arcade is U-shaped and the palate is deep

Fig. 4 Basal view.

and broad. The teeth that are present include P³, P⁴ and M¹ on the right, and the stump of P⁴ as well as M¹, M² and M³ on the left. The dimensions of the teeth are given in Table 2. All the teeth are heavily worn, with no trace of the cusp and fissure pattern on any tooth. Dentinal exposure is present on all the molars and all the teeth have suffered from post-mortem damage. The nasal aperture is pear-shaped and there is evidence of the presence of a nasal spine.

Table 2 Dimensions of the teeth*

		1 ¹	1 ²	C	P ³	P ⁴	M ¹	M ²	M ³
Left	B/L breadth	—	—	—	—	Roots only	11.5	—	10.5
	M/D length	—	—	—	—	—	10.0	—	10.0
Right	B/L breadth	—	—	—	9.5	9.8	12.5	—	—
	M/D length	—	—	—	7.0	7.0	10.8	—	—

*All the teeth are heavily worn and damaged.

In frontal view the zygomatic processes both take off laterally well above the alveolar margin and angle sharply laterally, giving breadth to the face. In lateral view the face shows a marked degree of subnasal prognathism so that the anterior dentition would have projected to a considerable degree. The frontal process of the maxilla on the left is broken, preventing articulation of the face with the cranial vault. The distortion of the frontal bone has also made correct positioning of the two major fragments impossible for all views of the skull.

The final assessment of the affinities of the Laetoli Hominid 18 skull must await a full study including anatomical comparisons and metrical analysis. From a preliminary examination, however, there is little doubt that it should be regarded as an early East African example of sub-Saharan *H. sapiens*, of particular interest because of its good state of preservation including the presence of its facial structure. The skull shows a number of points of resemblance with the African skulls known as Omo I, Omo II (ref. 6), Broken Hill (Kabwe), Saldanha, Bodo⁷ and Ndutu^{8,9}; its anatomical features are mixed in that it has some modern characters and some that are archaic. The general expansion of the vault, the rounded form of the occiput and the low position of the inion are modern features whereas the frontal flattening, the supraorbital torus, the small mastoids, the occipitomastoid crest and its general thickness are archaic features.

The dating of the skull also adds considerably to its importance as it places the fossil near to the root of the evolution of *H. sapiens* in East Africa out of the early *H. erectus* stock represented by Olduvai Hominid 9 and KNM-ER 3733. The *H. erectus*/*H. sapiens* transition is still poorly documented despite the recent finds from East Africa, notably the Bodo skull and the skull from Ndutu. The recovery of Laetoli Hominid 18 adds to this growing sample and makes an important contribution to our understanding of the evolution of *H. sapiens* in sub-Saharan Africa.

We thank the Government of Tanzania for permission to conduct field research in Tanzania, the Director of Antiquities, Mr A. A. Mturi, for his help and cooperation, Mr A. J. N. Mgina, Ngorongoro Conservation Authority, for his kindness, and the National Geographic Foundation, the Research Endowments Committee of St Thomas' Hospital and the WHO for their support.

Aggressive tusk use by the narwhal (*Monodon monoceros* L.)

H. B. Silverman & M. J. Dunbar

Marine Sciences Centre, McGill University, Montreal, Canada H3A 2B2

The narwhal, an Arctic odontocete, has two horizontally embedded teeth at birth¹. In males and a few females, the left tooth erupts at the end of the first year (K. A. Hay, personal communication) and develops into a spiralled tusk, which can be up to 260 cm long. It has been suggested that the tusk is used to disturb potential benthic prey²; to pierce prey before killing³; to pierce thin ice to make breathing holes^{4,5}; as a defensive weapon⁶; as a cooling mechanism⁶, and as a sound transmitter^{7,8}; but it is most probably used in display or fighting⁹⁻¹³. There is no mention in the literature of overt aggressive behaviour between narwhals or of scars on narwhals. We have found many scars on adult male narwhals. These, together with the high incidence of broken tusks in adult males and the burst of tusk growth at sexual maturity indicate that tusks are used in aggressive encounters.

Narwhal behaviour was observed from the ice and from a cliff on northern Baffin Island in the eastern Canadian Arctic during three field seasons, from June to October of 1976-1978. Narwhal specimens, which were provided by Inuit hunters, were sampled throughout the field seasons. We measured body length, tusk length, girth and weight, and counted from photographs the number of scars visible in a frontal view on the forehead and above the mouth of each sample.

Narwhals cross their tusks^{3,9}, and strike them against one another (R. Gray cited in ref. 14). We frequently observed narwhals cross tusks above and below the water surface (Fig. 1). Tusk crossing was often accompanied by a great deal of social behaviour, which is described by Silverman¹⁵. Agonistic behaviour, indicated by abrupt and quick movements, was rare. We propose that the observed behaviour patterns are components of mating and rutting behaviour sequences. Such behaviour, which was observed outside the mating season (mating is from March to May (ref. 16 and unpublished results of K. A. Hay)), may assist juveniles to develop skills for adult sexual roles, and may also communicate dominance rank.

Fig. 1 Drawing of two male narwhals crossing tusks above the back of a third narwhal.

Fig. 2 Relation between body length and head scar count of male narwhals. Regression equation is: $y = 1.576 \times 10^{-12} x^{4.953}$; $r = 0.756$; y, head scar count; x, body length in cm; n, 44.

The mean number of scars on the heads of adult males was significantly greater than that on adult females ($P < 0.001$). Males become sexually mature at body lengths of about 400 cm (K. A. Hay, unpublished), at which time tusk size (girth, weight and length) increases rapidly¹⁵. Large numbers of scars on the head occur only on male narwhals longer than 420 cm, well after sexual maturity is attained (Fig. 2).

Of the 39 adult males sampled, 61.5% had broken tusks (distal end broken off), whereas only 10.3% of the 29 juvenile male samples had broken tusks. One of our samples, an adult male, had the tip of a tusk, 9 cm long, embedded in its left upper jaw beside the base of its own tusk. We observed a large scar at the site of embedding and the head was covered with scars. Only one other similar finding has been reported¹⁷. Brown¹⁸ and Porsild¹⁹ occasionally recorded broken tusks with tusk tips jammed into the pulp cavities at the sites of the breaks. Dow and Hollenberg⁶ suggested that the deposition of reparative dentine could account for the tusk 'fillings'. We agree with Porsild¹⁹ that these 'fillings' are tusk tips; the photograph in his paper is convincing. If reparative function accounted for the tusk 'fillings', they should occur more often.

Scars occur in most, if not all, odontocete species²⁰⁻²². Spacing of scars often corresponds with tooth spacing of the same species²¹. Observations of captive odontocetes show that biting and subsequent scarring occur during play, sex and aggression²³. The presence of many scars on the heads of adult males, tusk crossing behaviour, rapid tusk growth at sexual maturity, large proportion of broken tusks in adult males, and the discovery of a tusk tip embedded in the jaw of a male strongly indicate that the tusk is used in intraspecific aggression, most probably during the mating season when male-male competition is expected to be most intense.

Synaptic mechanisms involved in responses of chromaticity horizontal cells of turtle retina

Marco Piccolino*, Jacques Neyton & Hersch M. Gerschenfeld†

Laboratoire de Neurobiologie, Ecole Normale Supérieure, 46 rue d'Ulm, 75230 Paris, Cedex 05 France

Chromaticity-type horizontal cells^{1,2} are interneurons intervening in the first steps of colour-coding information in the vertebrate retina. In turtle retina, the most commonly found of these cells are the red/green horizontal cells (R/G-HCs)³ which are hyperpolarised by green light stimuli and depolarised by red ones. The hyperpolarisation of the R/G-HCs by green light results from a direct input from green cones which are hyperpolarised by green light⁴. The depolarisation of R/G-HCs by red light has been interpreted by Fuortes and Simon⁴ as a consequence of the depolarisation of the green cones due to the activation of a polysynaptic circuit (red cones to L-horizontal cells (L-HCs) to green cones) involving a negative feedback effect of L-HCs on the green cones. Feedback depolarisations of cones result from an increase of the cone calcium conductance which may become regenerative and give rise to spikes^{6,7}. Moreover, prolonged activation of the feedback mechanism of L-HCs on cones in the presence of Sr^{2+} ions in the extracellular medium evokes a repetitive discharge of spikes in cones⁸. In the present work, the effect of Sr^{2+} ions on the responses of both green cones and R/G-HCs have been analysed to test the Fuortes and Simon hypothesis. We have found that in Sr^{2+} media, red light stimuli covering a large retinal area elicit both a repetitive discharge of spikes in the green cones and trains of depolarising transient potentials, probably postsynaptic potentials, in the R/G-HCs. Such results support the idea that feedback depolarisation of the green cones is responsible for the depolarising responses of R/G-HCs to red light.

The experiments were carried out on eyecup retina preparations from the turtle *Pseudemys scripta elegans* placed on a suitable chamber and continuously superfused with a bicar-

bonate saline solution⁹ bubbled with a mixture of 95% O_2 + 5% CO_2 . SrCl_2 was added to the saline without molarity compensation. Intracellular recordings were made with 4 M potassium acetate-filled micropipettes (resistance 200–600 M Ω), connected through an amplifier to a cathode ray oscilloscope and to both tape and pen recorders. The retina was stimulated with a double-beam photostimulator; the light stimuli could be modified by interposition of neutral density and/or interference filters.

As Fuortes *et al.*³ previously described, stimulation with deep red lights covering large retinal fields depolarises the green cones and, in some cases, evokes an initial spike response. This is shown in Fig. 1a₁, where a green cone responded to a large spot of red (700 nm) light by a spike followed by a slight hyperpolarisation. Stimulation of the same area with a 550-nm light evoked a large hyperpolarisation (Fig. 1a₂).

Several minutes after adding 6 mM SrCl_2 to the saline bathing the retina, little change was observed in the responses to green stimuli (Fig. 1b₂), but the large red spot then evoked, almost at the dark potential level, a repetitive discharge of spikes of 25 mV showing large undershoots (Fig. 1b₁). As previously demonstrated^{6–8}, such spikes result from a regenerative increase in conductance across Ca^{2+} channels in the cone membrane and are the consequence of the activation of a feedback connection from the L-HCs⁵. As in the case of all the spikes evoked in cones through the feedback mechanism, the hyperpolarisation of the cone by either inward current injection or appropriate light stimulation can cause partial or total block of the spikes^{7,8}. This is shown for the same green cone in Fig. 1b₃ using a green light stimulus and in Fig. 1b₄ by injecting an inward current pulse.

In the Sr^{2+} -treated retina, in parallel with the appearance of spikes in green cones, trains of transient depolarising potentials were observed in the R/G-HCs. Figure 2 shows records

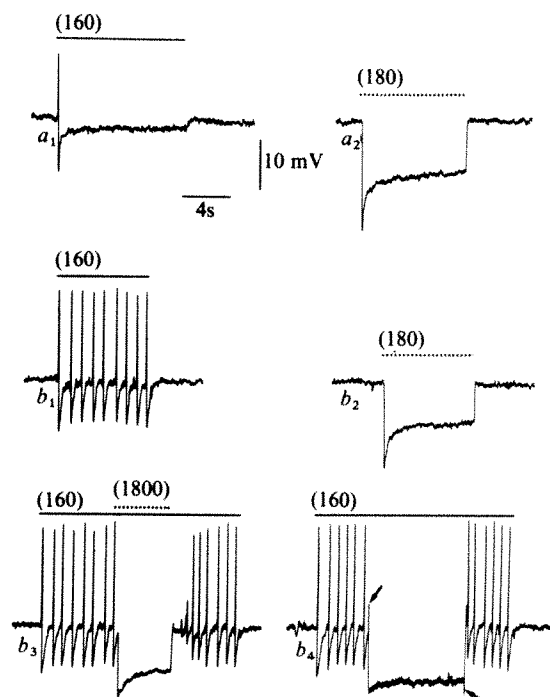

Fig. 1 Responses of a green cone to monochromatic light stimuli. In this and Figs 2 and 3, the stimuli were large spots of 3,700 μm diameter. The solid line traces above the responses indicate the duration of red (700 nm) stimuli, whereas the dotted line traces indicate the green (550 nm) stimuli. The numbers in parentheses, over the stimulus traces when multiplied by 10^3 give the quantum flux in photons $\mu\text{m}^{-2} \text{s}^{-1}$. a₁, a₂, Control recordings in normal saline. b₁–b₄, Responses of the cone during application of 6 mM Sr^{2+} . In b₄ an inward current of 0.2 nA was applied, between the arrows, through the recording microelectrode using a bridge circuit.

Fig. 2 Responses of a green cone (a-c) and a R/G-HC (d-f) recorded from the same retina bathed in 6 mM Sr^{2+} -containing medium. The wavelength of the light stimuli used in each aligned pair of recordings are indicated at the top. The quantum flux for all stimuli was 170×10^3 photons $\mu\text{m}^{-2} \text{s}^{-1}$.

obtained from a green cone and from a R/G-HC, recorded in the same Sr^{2+} -treated retina. Again, as in Fig. 1, large field stimulation with either 700- or 650-nm wavelength light evoked a repetitive discharge in the green cone (Fig. 2a, b). The same stimuli evoked prolonged depolarising responses in the R/G-HCs (Fig. 2d, e) consisting of an initial peak followed by a plateau phase on which was superimposed a train of transient depolarising potentials showing frequencies similar to those of the spikes in the green cones (Fig. 2d, e). In contrast, stimulation of the same retinal area with 550-nm light evoked only hyperpolarising responses in both the green cones and the R/G-HCs either before or during Sr^{2+} application (Fig. 2c, f).

Similar results were observed in 4 green cones and in 21 R/G-HCs. The frequency of the transient depolarising potentials in the R/G-HCs corresponded to that of the spike discharge in the green cones ($0.5\text{--}2 \text{ s}^{-1}$) when using the same stimuli and their amplitude varied between 2 and 10 mV. In most cases it was possible to show that the depolarisation of the R/G-HC membrane potential beyond the dark level was not necessary for the appearance of the transient depolarising potentials. This is illustrated in Fig. 3a in which large spots of 650-nm light evoked a train of depolarising potentials at a membrane potential close to the dark level. Furthermore, these depolarising transients could also be observed at membrane potentials more hyperpolarised than the dark level. Thus, when the same red stimulus was presented to the cell in the course of an hyperpolarisation elicited by a prolonged green light stimulus it evoked a large prolonged depolarising response whose plateau level did not reach the dark potential. The depolarising transients were, nevertheless, present and their amplitude even seemed to be increased (Fig. 3b). In Fig. 3c the same R/G-HC was stimulated with the same red stimulus during a rather prolonged period during which green stimuli of the same diameter, at different intensities, were intermittently combined with the red light. The two less intense green stimuli elicited hyperpolarising responses and the amplitude of the depolarising transients increased with the cell hyperpolarisation. However, the most intense green stimulus evoked a much larger hyperpolarisation and the disappearance of the depolarising potentials. It also blocked the repetitive spike discharge elicited by 650-nm light in green cones.

In two experiments using two independent microelectrodes, simultaneous recordings could be obtained from both a R/G-HC and a large-field L-HC. In the presence of Sr^{2+} in the

medium no depolarising transients could be evoked in the L-HC by stimuli which induced the appearance of transient depolarising potentials in the R/G-HC. Another point which was carefully investigated in Sr^{2+} -treated retinas was the existence of a possible relationship between the spikes that can be discharged in red cones through the activation of the feedback mechanism⁶⁻⁸ and the depolarising fluctuations evoked by red stimuli in the R/G-HC. We found that depolarising potentials in the R/G-HC could be evoked by stimuli which did not evoke spikes in the red cones, and conversely, stimuli which did evoke spikes in red cones could fail to induce the appearance of depolarising fluctuations in the R/G-HC. These results exclude any correlation between the appearance of feedback spikes in red cones and the depolarising potentials in the R/G-HC.

Our results show that in Sr^{2+} -treated turtle retinas, red light stimuli which elicit repetitive discharge of spikes through the feedback mechanism in green cones also evoke the appearance of depolarising potentials in the R/G-HCs. The spikes in the green cones are due to a regenerative increase in conductance through Ca^{2+} -membrane channels.

What is the nature of the depolarising transient potentials observed in the R/G-HCs? It seems unlikely that these depolarising potentials could be regenerative responses triggered by the sustained depolarisations evoked by red light in the R/G-HCs because such sustained depolarisations are not necessary for the depolarising transients to appear, and because these deflections can be elicited at membrane potentials more hyperpolarised than the dark potential. In contrast, many of the features of the depolarising potentials in the R/G-HCs are consistent with the idea that they are postsynaptic potentials due to phasic transmitter release evoked by the spikes in the green cones. The depolarising transients only appear in Sr^{2+} -treated R/G-HCs and only in response to stimuli which evoke spike discharge in the green cones, the trains of depolarising potentials in R/G-HCs showing a frequency similar to those of the cone spikes and becoming blocked by light stimuli which suppress the spikes in the green cones. Moreover, when the R/G-HCs are hyperpolarised by light stimuli which do not block the spikes in green cones, the amplitude of the depolarising potentials increase. Such behaviour is reminiscent of the classical depolarising synaptic potentials.

The present experiments, therefore, strongly suggest that the depolarising deflections evoked in the Sr^{2+} -treated R/G-HCs

Fig. 3 Responses from an R/G-HC recorded in a retina bathed in a 6 mM Sr^{2+} -containing medium. The full line traces above the recordings indicate the duration of red (650 nm) stimuli whereas the dotted lines indicate the duration of green (550 nm) stimuli. The numbers in parentheses, when multiplied by 10^3 give the quantum flux in photons $\mu\text{m}^{-2} \text{s}^{-1}$.

by red lights are depolarising synaptic potentials secondary to presynaptic spikes evoked through the feedback mechanism of L-HCs on the green cones.

What is the relevance of these results obtained in Sr^{2+} -treated retinas to the known properties of the R/G-HC responses in the normal retina? According to Fuortes and Simon, (1) R/G-HCs receive their only direct input from the green cones; (2) a green stimulus hyperpolarises the green cones, then the R/G-HC; (3) green cones are almost unaffected by red light impinging on them; (4) red illumination of a large area of the retina hyperpolarises the red cones, thus hyperpolarising the L-HCs which receive their main input from red cones; (5) the L-HCs send back their signal on to the green cones, depolarising them, in consequence depolarising the R/G-HCs. The recent anatomical studies of Leeper^{10,11} are consistent with this hypothesis. This author identifies the R/G-HCs with one morphological type of horizontal cell (H2) which is mainly in contact with green cones, and describes another type of horizontal cell (H1-CB) which would be responsible for the feedback effects on the green cones.

From the known properties of photoreceptor synapses¹²⁻¹⁶, hyperpolarisation by green light is expected to suppress the transmitter release from green cones whereas their feedback depolarisation by red light, which involves an increase in Ca^{2+} conductance⁶⁻⁸, is expected to increase the release of transmitter. Our results thus give further support to the hypothesis of Fuortes and Simon, as they indicate that stimuli which evoke depolarising responses in R/G-HCs cause a powerful activation

of the feedback circuit affecting the green cones and when this feedback activation gives rise to a repetitive discharge of Ca^{2+} spikes, depolarising synaptic potentials are actually observed in R/G-HCs. Therefore, the release of a single transmitter from green cones, depressed by the hyperpolarisation evoked by green light and increased by the red light activation of the feedback circuit, can account for the opposite polarity of the responses of the R/G-HCs to such stimuli.

We thank Mr Bernard Lacaille for technical assistance. Postsynaptic effects of ethanol at the frog neuromuscular junction

Ronald J. Bradley, Klaus Peper & Raimund Sterz

II. Physiologisches Institut der Universität des Saarlandes, D-6650 Homburg/Saar, FRG

The molecular mode of action of alcohol in the central nervous system (CN) is unclear¹. The effects of ethanol on axonal action potentials can only be measured at concentrations which are very much higher than those required to produce central effects². At the frog neuromuscular junction similar concentrations increase the open time (τ) of the ion channel associated with the nicotinic acetylcholine (ACh) receptor³. We have now investigated the effect of ethanol on the postsynaptic membrane of the frog neuromuscular junction by measuring equilibrium dose-response curves for the interaction between the neurotransmitter (ACh) and the ACh receptors. Using this system, we found that ethanol produces significant changes in receptor function. Moreover, we found that at an ethanol concentration which can be physiologically tolerated by man (0.2%) the dose-response curve is measurably affected.

The neuromuscular junction of the cutaneous pectoris muscle in the frog (*Rana esculenta*) is ideal for such studies⁴. The muscle can be dissected to a monolayer of fibres⁵, and the endplate region of the cell membrane which contains the nicotinic ACh receptors can be readily detected with Nomarski optics⁶. The cell membrane is voltage clamped by a conventional two-electrode system and an iontophoresis pipette for the experimental delivery of ACh is placed at a known distance (z) above the finger-like endplate area. A current pulse of known duration and amplitude is applied to the pipette, resulting in the release of a controlled amount of ACh from the tip⁷. The ACh

diffuses to the receptors, thus giving rise to a transient increase in membrane current which is due to the opening of ion channels associated with the receptors^{8,9}. In defined conditions it can be shown that the response is in equilibrium with the concentration of ACh at the receptor site^{10,11}.

Figure 1a shows a typical current response produced by an iontophoretic pulse of ACh in three concentrations of ethanol at the same endplate. The peak current (I_p) in this response was almost doubled in the presence of only 0.2% ethanol. The time to peak (t_p) did not change with the application of ethanol, indicating that saturation of the endplate receptors had not been reached¹⁰. In this condition it was also possible to determine the Hill coefficient (n_H) from the actual time course of the ACh response¹⁰. Such an analysis showed that ethanol had no effect on the value of n_H .

If, in an experiment like that shown in Fig. 1a, one plots the peak amplitude of the response (I_p) against the charge Q (duration multiplied by amplitude of releasing pulse) for different charges, then a dose-response curve is obtained (Fig. 1b). These curves are highly reproducible^{11,12}. From the charge through the pipette it is possible to calculate the amount of ACh which is released and by use of the diffusion equation the concentration profile at the endplate may be defined. From the equilibrium dose-response curve the following parameters may be calculated: (1) the maximum conductance, g_{\max} , per unit length of the terminal (in $\text{nS } \mu\text{m}^{-1}$); (2) the apparent dissociation constant K (in μM) which reflects both the binding and the conformational change of the drug-agonist interaction; (3) the Hill coefficient, n_H . These three parameters completely describe the equilibrium reaction between ACh and the receptors. The evaluation of the parameters of equilibrium dose-response curves is dependent on the use of a kinetic model for the drug-receptor interaction. The model and procedure used here have been explicitly described elsewhere¹², and for an alternative method see ref. 13.

Figure 1b shows a typical ACh dose-response curve obtained before and after the addition of 2% ethanol. The solid lines are the standard curves which provide the best fit to the data. The curve is shifted to the left, signifying that a fixed dose of ACh has a greater effect in the presence of ethanol. It can be seen that the

Fig. 1 *a*, Influence of different concentrations of ethanol on endplate currents produced by iontophoretic release of ACh from a pipette located 25 μm above a single linear endplate terminal. The two clamping electrodes were placed on either side of the endplate close to the ACh pipette. The iontophoretic pulse was initiated at time 0. The pulse duration was 1.5 ms and the pulse height 300 nA (charge: 0.45 nC). Ethanol (Merck, 96 vol %) at the above concentrations was diluted in Ringer solution and exchanged into the bath for each measurement. All measurements were obtained at the same endplate in identical conditions. The time to peak (t_p) for each response was unchanged, signifying that the ACh pipette always remained at the same location. The Ringer solution had the following composition (mM): NaCl 115, KCl 2.5, CaCl_2 1.8, phosphate buffer 5, pH 7.1. The membrane potential was -80 mV and the bath temperature was 18°C . The effects of ethanol at any concentration could be reversed by returning to normal Ringer solution whereupon the maximum current (I_p) of the response returned to the control value. *b*, ACh dose-response curves at a single endplate before and after the addition of 2% ethanol to the Ringer solution. The maximum current (I_p) for each response and the associated time to peak (t_p) were plotted against the charge passed through the ACh-releasing pipette (log-log scale). The membrane potential was -80 mV and the temperature was 18°C . The Hill coefficient, n_H (2.8), was measured from the slope of the line at low drug concentrations and was not changed by the addition of 2% ethanol. The solid lines are the theoretically derived curves ($n_H = 2.8$) which permit the calculation of g_{max} and K . The time (t_p , lower trace) to peak current (I_p , higher trace) remains constant for low doses and increases at higher doses. The parameters for the control dose-response curve were n_H 2.8, g_{max} $176 \text{ nS } \mu\text{m}^{-1}$, K $36 \mu\text{M}$, and for 2% ethanol n_H 2.8, g_{max} $168 \text{ nS } \mu\text{m}^{-1}$, K $13.6 \mu\text{M}$ (see Table 1). *c*, Comparison of the apparent dissociation constant K between controls and different concentrations of ethanol for ACh dose-response curves. Each K value was computed for a control dose-response curve and a dose-response curve after the addition of ethanol measured at the same endplate. The ratios were averaged for several different endplates and the graph shows the respective mean values \pm s.e.m. (see Table 1).

Fig. 2 Normalised power spectrum (log-log scale) calculated from ACh-induced endplate current noise before and after the addition of 2% ethanol at the same endplate. The ACh pipette was located $70 \mu\text{m}$ above the endplate and ACh was continuously released, resulting in a constant mean endplate current, μ_1 . The resulting noise was filtered between 3 and 1,000 Hz, digitised at 2,000 Hz and stored in frames of 1,024 points. The power spectrum was averaged from 20 frames. In each case a background control spectrum in the absence of ACh was subtracted from the ACh-induced spectrum. The solid lines are the theoretical lorentzian functions which provide the best fit to the data. The mean channel lifetime (τ) was obtained from each curve by the formula $\tau = 1/(2\pi f_c)$, where f_c is the cutoff frequency designated by the arrows above each curve. The single channel conductance was obtained from the formula $\gamma = G(0)/[4\mu_1(V_m - V_{\text{eq}})\tau]$, where V_{eq} is the ACh null potential (-5 mV), V_m is the membrane potential (-80 mV) and $G(0)$ is the zero frequency amplitude. The temperature was 18°C . For the control spectra above, $G(0) = 1.67 \times 10^{-22} \text{ A}^2 \text{ Hz}^{-1}$, $\mu_1 = -26$ nA, $f_c = 174$ Hz, $\tau = 0.92$ ms and $\gamma = 23.4$ pS. For the spectra in 2% ethanol, $G(0) = 4.39 \times 10^{-22} \text{ A}^2 \text{ Hz}^{-1}$, $\mu_1 = -29$ nA, $f_c = 66$ Hz, $\tau = 2.4$ ms and $\gamma = 20.9$ pS. Noise analysis at four different endplates before and after the addition of 2% ethanol showed that γ was reduced to 0.91 ± 0.06 (s.e.m.) of the control value and τ was increased to 2.2 ± 0.14 (s.e.m.) of the control value.

slopes of both curves are identical, and thus that the Hill coefficient or cooperativity of the receptor response to ACh is unchanged. This value of 2.7 implies that three or more (perhaps four) ACh molecules are required to bind for one channel to open. The value of K was dramatically reduced, as is evident from the shift in the dose-response curve. In Fig. 1c the relative change in K is plotted against the ethanol concentration, showing that at the lowest concentration of 0.2%, a reduction of 10–20% in K is produced, corresponding to a doubling of the response in the linear part of the dose-response curve.

g_{max} Was not affected by 0.2% or 1% ethanol but was slightly reduced by 2% ethanol (Table 1) which would reflect either a reduction in the total number of channels capable of opening or in the size of the individual channel. This was tested by noise analysis, which showed that indeed the individual channel conductance (γ) was reduced by about 9% and that, in addition, the lifetime of the single channel (τ) was increased in 2% ethanol (Fig. 2). These changes in single channel properties are similar to the findings of Gage *et al.*³. The reduction of γ could, therefore, account for the slight reduction in g_{max} which we have observed in the presence of 2% ethanol.

We therefore conclude that the drastic increase of the post-synaptic response in ethanol as shown in Fig. 1a is due to a reduction in K . Note that even a small change in K will result in a large change in I_p for a constant Q . This effect is due to the steep dependence of I_p on Q , the slope being equal to the Hill coefficient. However, with our method we cannot discriminate between whether only the conformational change or the binding step in the drug-receptor interaction or both have been affected by ethanol.

Dose-response curves are carried out using carbachol as agonist or with ACh after the inhibition of esterase by edrophonium gave a similar reduction in K in the presence of ethanol (Table 1). This effect of ethanol is, therefore, not due to an inhibition of cholinesterase, which could change the apparent dissociation constant. Note that the reduction of K in the

Table 1 Ratio of g_{\max} and K values \pm s.e.m. obtained in different concentrations of ethanol to control values for ACh and carbachol as agonist

Drug	$\frac{g_{\max}(\text{ethanol})}{g_{\max}(\text{control})}$	$\frac{K(\text{ethanol})}{K(\text{control})}$
Acetylcholine		
0.2% ethanol	1.00 ± 0.08 (4)	0.88 ± 0.06 (4)
1.0% ethanol	0.97 ± 0.07 (3)	0.63 ± 0.10 (3)
2.0% ethanol	0.93 ± 0.03 (8)	0.46 ± 0.03 (8)
2.0% ethanol		
+5 μM edrophonium	0.92 ± 0.06 (2)	0.48 ± 0.04 (2)
Carbachol		
2% ethanol	0.92 ± 0.06 (6)	0.62 ± 0.06 (6)

For each data point a dose-response curve was obtained at the same endplate before and after the addition of the corresponding concentration of ethanol. The average values for the parameters of the control dose-response curves were for ACh: $n_H = 2.7$, $g_{\max} = 169 \text{ nS } \mu\text{M}^{-1}$, $K = 27.8 \text{ } \mu\text{M}$ (corrected for ACh-esterase activity) and for carbachol: $n_H = 2.2$, $g_{\max} = 150 \text{ nS } \mu\text{M}^{-1}$, $K = 336 \text{ } \mu\text{M}$ (ref. 10). Numbers in parentheses refer to the number of fibres investigated.

presence of ethanol is greater with ACh as the agonist than with carbachol. As already reported¹², control dose-response curves for carbachol give a lower Hill coefficient, a lower g_{\max} and a higher K than ACh (Table 1). Also, the reduction in g_{\max} in the presence of 2% ethanol is the same as for ACh as for carbachol, showing that the efficacy¹² of carbachol in relation to ACh is not changed.

A reduction of the dissociation constant K by ethanol concentrations as low as 0.2% (a value which can be found in an intoxicated human) could also be demonstrated on mammalian endplates (preliminary experiments on rat and mouse omohyoideus, not illustrated). Here the alcohol effect is even more pronounced.

Ethanol cannot be expected to improve neuromuscular transmission which already has a high safety factor, in healthy specimens. However, it may very well have a positive effect in patients in whom the neuromuscular transmission is impaired (for example, in cases of myasthenia gravis). This positive effect of ethanol could indeed be demonstrated in stimulation electromyography of myasthenic patients, where ethanol concentrations as low as 0.05% proved to be effective¹⁴.

One might speculate that the ability of ethanol to improve the binding of ACh to neurotransmitter receptors could also have highly significant effects in central synapses and thus influence intraneuronal communication which gives rise to normal behaviour.

We thank Mr H. Ehrler, Mrs D. Kriesel and Mrs C. Scheidt for their help. This work was supported by the Deutsche Forschungsgemeinschaft SFB 38, project N.

Stimulation of hypothalamic nuclei has differential effects on lipid synthesis in brown and white adipose tissue

Takashi Shimazu & Akira Takahashi

Division of Neurochemistry, Psychiatric Research Institute of Tokyo, 2-1-8 Kamikitazawa, Setagaya-ku, Tokyo, Japan

The hypothalamus has been implicated in the development of obesity in both humans¹ and experimental animals². The syndrome of hypothalamic obesity results from destruction of the ventromedial region of the hypothalamus³, and investigations of the influences of the hypothalamus on lipid metabolism have been directed chiefly at understanding the mechanism underlying obesity^{2,4,5}. There have been few studies of the effects on lipolysis and lipogenesis in adipose tissue after stimulation of the ventromedial and lateral hypothalamic (LH) nuclei, which may act reciprocally in regulating certain types of peripheral metabolism⁶⁻⁹. We have shown¹⁰ that electrical stimulation of the ventromedial hypothalamic nucleus (VMH) causes lipolysis in adipose tissue, detected by a rapid rise in the plasma glycerol concentration, whereas electrical stimulation of the LH has no such effect. It is not known whether hypothalamic stimulation of either the VMH or the LH affects lipogenesis in adipose tissue. We have investigated this problem by measuring the incorporation of tritium from $^3\text{H}_2\text{O}$ into fatty acids *in vivo*. This is the most reliable method for measuring the rate of fatty acid biosynthesis, because it is independent of the carbon precursor^{11,12}. Surprisingly, electrical stimulation of the VMH enhanced fatty acid synthesis in brown adipose tissue, but not in white adipose tissue or the liver, without the intervention of insulin secretion. Electrical stimulation of the LH, however, had no appreciable effect on lipid synthesis in either type of adipose tissue.

Female Wistar rats weighing about 230 g were housed in individual cages and given free access to laboratory chow and water. The hypothalamus was stimulated, through chronically implanted electrodes, without disturbing the animals' behaviour. Bipolar electrodes of insulated 160- μm wire were implanted stereotactically and unilaterally in the VMH or the LH of rats under pentobarbital anaesthesia. The electrodes were connected to a small plug which was anchored firmly to the skull⁷. The position of the tip of the electrode was verified microscopically in brain sections made when the experiments were complete. Two weeks after implantation, electrical stimuli, consisting of monophasic square pulses of 0.1-0.3 ms duration at 100 Hz with an amplitude of 6 V, were applied to the hypothalamus. Control rats had similarly implanted electrodes but no electrical stimuli were applied. An interval timer was connected to the stimulator to allow repeated stimulation for 30-s periods, once every minute. After 10 min of intermittent hypothalamic stimulation, the rats were injected with $^3\text{H}_2\text{O}$ and 30 min later they were killed. The interscapular adipose tissue (brown fat), the parametrial and retroperitoneal adipose tissues (white fat), and the liver were removed and frozen on dry ice. Total lipids from each tissue were hydrolysed, and after extraction of the fatty acids radioactivity was measured (Fig. 1). In later experiments, some rats were made diabetic (blood glucose levels at the time of death $>400 \text{ mg dl}^{-1}$) by intravenous injection of streptozotocin (65 mg per kg) 24-26 h before hypothalamic stimulation. To minimise the effects of environmental temperature¹³ and of circadian variation¹⁴ on lipogenic activity in adipose tissue, all experiments were performed at $25 \pm 2^\circ\text{C}$ and between 10.00 h and noon, and the animals were not fed for 3 h before the experiments.

The rate of fatty acid synthesis in control rats was about four times greater in brown (interscapular) adipose tissue than in white (parametrial and retroperitoneal) adipose tissue (Fig. 1). With electrical stimulation of the VMH, the rate increased more (about 2.3 times that of unstimulated controls) in the interscapular adipose tissue ($P < 0.05$), but not in the white adipose tissue. Slightly increased rates observed in parametrial and retroperitoneal adipose tissue were not statistically significant ($P > 0.05$). Electrical stimulation of the LH did not appreciably affect lipid synthesis in either type of adipose tissue. Fatty acid synthesis in the liver was not affected by stimulation of the VMH or the LH.

The differential effects of VMH stimulation on lipogenesis in brown and white adipose tissues are probably not mediated by increased secretion of insulin, a pancreatic hormone that stimulates lipid synthesis, because electrical stimulation of the VMH suppressed rather than increased insulin secretion^{8,15}, and if insulin output had increased, fatty acid synthesis would have been enhanced equally in brown and white adipose tissues and liver. When rats were injected with insulin (0.2 U, intraperitoneally), a marked increase in tritium incorporation into fatty acids was observed consistently in all three tissues (data not shown). Table 1 shows the effects of injury to the pancreatic β cells by intravenous injection of streptozotocin before stimulation of the VMH. The appearance of hyperglycaemia (more than 400 mg dl⁻¹) and glucosuria confirmed that insulin secretion was suppressed.

The rate of fatty acid synthesis in the two types of adipose tissue and in the liver of diabetic control rats was reduced to below half the values in healthy control rats, possibly due to the absence of the lipogenic action of insulin. Nonetheless, electrical stimulation of the VMH of the diabetic rats markedly increased lipid synthesis in brown adipose tissue ($P < 0.05$). Again, there was no significant increase in the lipogenic response in either

Fig. 1 Effect of hypothalamic stimulation on fatty acid synthesis *in vivo* in adipose tissues and liver. The VMH or LH was stimulated intermittently for 10 min and then the rats were injected intraperitoneally with 3 mCi of ³H₂O in 0.3 ml of 0.9% NaCl solution. After another 30 min period of stimulation, the rats were killed and the interscapular, retroperitoneal and parametrial adipose tissues and the liver were removed and frozen rapidly, and the incorporation of tritium into their fatty acids was measured. Lipids were extracted by homogenising a portion (1 g) of each frozen tissue with 19 ml of chloroform-methanol (2:1, v/v). For isolation of radioactive fatty acids, the lipid extract was washed once with 0.13 M NaCl solution and three times with methanol-0.13 M NaCl-chloroform (50:47:3, by vol), evaporated under nitrogen, saponified with 5 N NaOH at 80°C for 3 h, acidified with 10 N H₂SO₄, and then extracted three times with petroleum ether. The final extract was evaporated and its radioactivity was counted in toluene scintillation solution¹². The rate of fatty acid synthesis was calculated from the radioactivity in fatty acids and in the plasma obtained at the time of death¹⁴. Columns and bars are means and standard errors of values in six to eight animals. Open columns, controls; hatched, LH; solid, VMH.

Table 1 Lipogenic responses of adipose tissues and liver to stimulation of VMH in streptozotocin-induced diabetic rats

	Diabetic control	Diabetic with VMH stimulation
Interscapular adipose tissue	0.48 ± 0.04	1.11 ± 0.12*
Retroperitoneal adipose tissue	0.15 ± 0.01	0.19 ± 0.01
Parametrial adipose tissue	0.16 ± 0.02	0.20 ± 0.02
Liver	0.48 ± 0.05	0.37 ± 0.04

Experimental conditions were as for Fig. 1, except that rats were made diabetic by injection of streptozotocin (65 mg kg⁻¹, intravenously) before they were stimulated electrically. Incorporation of tritium into fatty acids extracted from the adipose tissues and liver was measured, and the rate of fatty acid synthesis was expressed as μmol per g wet weight of tissue in 30 min. Results are means ± s.e.m. of the values in eight animals in each group.

*Significantly different from the unstimulated control group at $P < 0.05$.

retroperitoneal or parametrial white adipose tissue, and conversely fatty acid synthesis in the liver decreased slightly, though not significantly ($P > 0.05$), with stimulation of the VMH.

These results indicate that stimulation of the VMH enhances lipogenesis in brown adipose tissue preferentially, through a mechanism not involving insulin. This effect is probably mediated by sympathetic innervation of brown adipose tissue, because the VMH is presumed to be part of the sympathetic neural output from the hypothalamus^{8,16}. Brown adipose tissue has abundant sympathetic innervation with adrenergic fibres, which form nest-like networks around every fat cell¹⁷. On the other hand, white adipose tissue contains no adrenergic fibres except those related to the blood vessels¹⁸, and consequently it contains much less noradrenaline than does brown adipose tissue. Therefore, noradrenaline may be a mediator of the effect of VMH stimulation on lipogenesis in brown adipose tissue. This idea is supported by preliminary results showing that intraperitoneal injection of noradrenaline (3×10^{-7} mol) into rats increased the rate of fatty acid synthesis in interscapular adipose tissue. However, it is also possible that some lipogenic factor(s) released from the hypothalamus acts on brown fat cells; such a factor has been found in an extract of bovine hypothalamus¹⁹.

Our results, together with the previous observation of increased lipolysis in adipose tissue after stimulation of the VMH¹⁰, suggest that both the breakdown and resynthesis, that is, the turnover, of triglycerides in brown adipose tissue, but not in white adipose tissue, are accelerated by stimulation of the VMH. Because brown adipose tissue is an important fat depot for physiological lipolysis mediated by the sympathetic nerves, especially during cold acclimatisation, this could also explain the increased lipid turnover in the brown adipose tissue of cold-acclimatised animals^{20,21}.

L-Glutamic acid (Glu) and L-aspartic acid (Asp) are putative excitatory transmitters in the mammalian central nervous system (CNS)¹⁻³. Receptors at Glu- and Asp-mediated synapses are presumably different^{4,5}, and a prerequisite for the identification and characterisation of such sites is the availability of specific antagonists and agonists. Among various potential Glu and Asp antagonists³⁻⁶ Glu diethyl ester (GDEE)⁷⁻⁹ and (D)- α -aminoadipic acid (α -AA)⁹⁻¹³ show some selectivity, the latter particularly towards excitation by *N*-methyl-Asp. Kainic acid (KA), a structural analogue of Glu, is a powerful excitant of CNS neurones¹⁴⁻¹⁶ that seems to interact with only a small proportion of Glu receptors⁵. Ibotenic acid (Ibo) is a powerful neuronal excitant^{9,17,18} also structurally related to Glu. Excitation by Ibo, however, is readily antagonised by α -AA, whereas GDEE has little or no effect¹³, suggesting that Ibo preferentially activates Asp rather than Glu receptors. Furthermore, excitation of neurones by Ibo is followed by a prolonged depression of excitability^{18,19} which is sensitive to bicuculline methochloride¹⁹, indicating that Ibo is probably converted by decarboxylation into muscimol²⁰ during microelectrophoretic ejection near CNS neurones. Thus, neither KA nor Ibo seem to have sufficient specificity to be useful compounds with which to study central Glu or Asp receptors. We describe here a new class of Glu agonist obtained by structural manipulation of Ibo (Table 1). Elongation of the side chain of Ibo by an additional methylene group and introduction of different ring substituents have led to isoxazole amino acids with carboxyl groups resistant to decarboxylation. A further aim of this homologation was to convert the apparent Asp agonist Ibo into a Glu agonist.

Experiments were carried out on lumbar dorsal horn interneurons and Renshaw cells of 11 cats anaesthetised with pentobarbitone sodium (35 mg per kg body weight intraperitoneally, supplemented when required). Extracellular action potentials were recorded by means of the centre barrel of seven-barrel micropipettes, and the compounds tested were administered electrophoretically as anions from aqueous solutions in the outer barrels of the micropipettes²¹. The approximate potency of each excitant was assessed relative to that of Glu on the basis of the electrophoretic current required to produce equal and submaximal excitatory effects on 3 to 19 neurones, taking into account the addition of NaCl (100–165 mM) to dilute solutions (10–50 mM) of strong excitants. Antagonism of amino acid excitation by GDEE and α -AA was tested in each case on 2 to 9 neurones as described previously^{12,13} using Glu and *N*-methyl-(D)-aspartic acid (NMDA) as reference excitants. As in these studies antagonism by either GDEE or α -AA was rarely completely specific, and in Table 1 'yes' indicates a consistent and significantly greater reduction of the effects of a particular excitant by one of the antagonists compared with the other.

Table 1

COMPOUND	EXCITATION OF CAT SPINAL NEURONES		INHIBITION OF KAINIC ACID BINDING	
	Rel. potency	Antagonism by GDEE	α -AA	IC ₅₀ values μ M
 (S)-Glutamic acid	++	Yes		0.41
 Ibotenic acid	++++		Yes	12.2
 (RS)-4-Methyl-ibotenic acid	++(+)		Yes	10.0
 (RS)- α -Amino-3-hydroxy-5-methyl-4-isoxazoleacetic acid (AMAA)	++		Yes	>100
 (RS)- α -Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)	+++++	Yes		>100
 (RS)-Homoibotenic acid	+(+)	Yes		>100
 (RS)-4-Methyl-homo-ibotenic acid	+++	Yes		>100
 (RS)-4-Bromo-homo-ibotenic acid	+++++	Yes		>100

The relative potency of the amino acids as excitants was determined microelectrophoretically as described in the text and shown in Fig. 1. The effects of the excitants are expressed relative to that of Glu (++) by the number of symbols indicating lower, equal, or greater activity, and (+) being of less value than +. Antagonism of the excitatory effects of the amino acids by GDEE or α -AA is indicated by 'yes'. For the ³H-KA binding assay procedure aliquots of rat brain synaptic membranes (0.8–1.2 mg of protein), isolated by a described procedure²³, were incubated in triplicate at 4 °C for 20 min in 2 ml 50 mM-Tris-citrate buffer (pH 7.1), which was 40 nM with respect to ³H-KA, and which contained varying concentrations of KA, Glu, or the listed isoxazole amino acids. After incubation the reaction was terminated by centrifugation for 10 min at 48,000g. The supernatant fluid was discarded, and the pellet was rinsed with two 5-ml portions of ice-cold distilled water. The pellet was suspended in 1 ml of water. To 0.8 ml of this suspension was added 10 ml of scintillation liquid (Insta-gel, Packard), and radioactivity was measured in a liquid scintillation counter (Beckman LS 250). Total specific ³H-KA binding (1,500 c.p.m. per mg of protein) was obtained by subtracting from the total bound radioactivity in the absence of inhibitor (2,225 c.p.m. per mg of protein) the amount not displaced by 100 μ M KA (725 c.p.m. per mg of protein). IC₅₀ values were estimated by examining the effects of at least four different concentrations of the inhibitor and performing log-probit analyses of the results. Log-probit analyses³⁰ and protein measurements³¹ were carried out using published procedures.

Fig. 1 The effects of GDEE and DL- α -AA on the excitation of the firing of two spinal interneurons by NMDA, (RS)-4-bromo-homoibotenic acid, AMPA and AMAA. *a*, NMDA (80 nA, 50 mM in 165 mM NaCl, pH 7), (RS)-4-bromo-homoibotenic acid (9 nA, 200 mM, pH 7), DL- α -AA (40 nA, 200 mM, pH 7), GDEE (30 nA, 200 mM, pH 3.5), all ejected microelectrophoretically as indicated by the appropriate horizontal lines. *b*, AMPA (6 nA, 200 mM, pH 7), AMAA (25 nA, 200 mM, pH 7), DL- α -AA (50 nA, 200 mM, pH 7), GDEE (20 nA, 200 mM, pH 3.5). Ordinates: firing rate, spikes s^{-1} . Abscissae: time, min.

The compounds listed in Table 1 were also tested as inhibitors of the sodium-independent binding of 3H -KA²² to synaptic membranes isolated from rat brains as previously described²³. (RS)-Homoibotenic acid and (RS)-4-bromo-homoibotenic acid²⁴, (RS)- α -amino-3-hydroxy-5-methyl-4-isoxazoleacetic acid (AMAA)²⁵, and (RS)-4-methyl-homoibotenic acid²⁶ were prepared by published procedures. The synthesis of the new compounds (RS)-4-methyl-Ibo and (RS)- α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) (see Table 1) will be published elsewhere.

The excitatory action of 4-methyl-Ibo was weaker than that of Ibo and slightly more potent than that of Glu. The effects of Ibo and 4-methyl-Ibo on all three neurones examined were reversibly antagonised by α -AA, whereas GDEE had little or no antagonistic effect. Excitation by 4-methyl-Ibo did not seem to be followed by depression, but as the corresponding decarboxylated compound, 4-methyl-muscimol, is a relatively weak neuronal depressant²⁷, *in vivo* production of this compound may not have been detectable in these experiments. Whereas homoibotenic acid was slightly weaker than Glu as an excitant, its ring-substituted derivatives were much more potent (Table 1). Thus, 4-bromo-homoibotenic acid was more potent than Ibo, which in turn was more potent than 4-methyl-homoibotenic acid. The excitatory effects of homoibotenic acid, 4-bromo-homoibotenic acid, and 4-methyl-homoibotenic acid were completely or partially antagonised by GDEE in a reversible way, but in no case were the excitatory effects of these compounds significantly reduced by α -AA (Fig. 1*a*).

Similarly, AMPA was a GDEE-sensitive, α -AA-insensitive neuronal excitant and was even more potent than 4-bromo-homoibotenic acid (Fig. 1*b*). Whereas AMPA is a Glu analogue, its lower homologue AMAA is structurally related to Asp. Accordingly, the excitatory effect of AMAA, which was similar in potency to that of Glu, was selectively reduced by α -AA. In

general, the neuronal excitations induced by the isoxazole amino acids listed in Table 1 were prolonged compared with that of Glu, suggesting that these compounds were not as effectively removed from the vicinity of the neurones as is Glu. Furthermore, depression was observed only after excitation by Ibo.

In agreement with previous findings, KA^{22,28,29} was found to be a potent inhibitor of 3H -KA binding with an IC_{50} of 0.013 μ M, whereas Glu and in particular Ibo were much weaker (Table 1). With the exception of 4-methyl-Ibo, which like Ibo was a weak inhibitor of 3H -KA binding, none of the isoxazole amino acids studied had any effect in this test system.

These *in vitro* and *in vivo* results suggest that AMPA, homoibotenic acid and its 4-methyl and 4-bromo derivatives excite cat spinal neurones by activating Glu receptors which are different from those on rat brain membranes which bind KA, and that this series of compounds may be useful for future pharmacological analyses of CNS Glu receptors.

In contrast to AMPA, in which the negative charges are separated by five carbon atoms, homoibotenic acid and its derivatives are not strict Glu analogues. Nevertheless, all of these heterocyclic amino acids seem to act on the same receptor, and introductions of ring substituents into homoibotenic acid result in much more potent excitants. The side chains of AMPA and of 4-methyl- and 4-bromo-homoibotenic acid are probably forced by the ring substituents into similar conformations which are readily recognised by the receptors. These steric effects of the methyl groups in AMPA and 4-methyl-homoibotenic acid and the similarity of the proposed resulting conformations are shown in Fig. 2. The depicted orientation of the side chain of AMPA is supported by X-ray crystallographic studies²⁶, and further studies along these lines may elucidate the 'receptor-active conformation(s)' of Glu.

We thank the Danish MRC for support and Dr T. R. Christiansen, Mrs P. Searle and Dr J. C. Bornstein for collaboration. Ibo was a gift from Dr N. Nakamura, NMDA from Dr J. C. Watkins and Mr B. Twitchin, and α -AA from Mr B. Twitchin.

Fig. 2 The structures of 4-methyl-homoibotenic acid and AMPA at physiological pH and their proposed conformations determined by the steric influences of the methyl groups.

Glucagon and glicentin immunoreactivity are topologically segregated in the α granule of the human pancreatic A cell

Mariella Ravazzola & Lelio Orci

Institute of Histology and Embryology, University of Geneva Medical School, 1211 Geneva 4, Switzerland

Glicentin is a 100-amino acid polypeptide purified from the porcine intestine¹ and containing the immunodeterminants of glucagon². We have previously reported³ the presence of glicentin immunoreactivity in the glucagon-containing, specific secretory granules (α granules) of the pancreatic and gastric A cell. With an improved immunocytochemical probe, the protein A-gold (pAg) technique⁴, we are now able to show that glucagon and glicentin-like material are topologically segregated in the α granule of the human pancreatic A cell.

Surgical specimens of the pancreatic tail were fixed in 4% glutaraldehyde in 0.1 M phosphate buffer, pH 7.4, dehydrated and embedded in Epon 812. Thin sections of the embedded blocks selected for the presence of islets of Langerhans were collected on Parlodion-coated nickel grids and processed for the pAg technique according to the method of Roth *et al.*⁴. The thin sections attached to the grids were incubated for 2 h at room temperature on a drop of anti-glucagon or anti-glicentin serum, washed carefully with phosphate-buffered saline (PBS) and further incubated for 1 h at room temperature with the protein A-gold complex. After a rinse in PBS and distilled water, incubated sections were double stained with 1% aqueous uranyl acetate and 1% lead citrate. The anti-glucagon serum was the 15K antiserum; 15K is a C-terminal anti-glucagon serum which does not react with extracts containing gut GLI's (R. H. Unger, personal communication). 15K was used in a 1:20 dilution. The specific anti-glicentin serum (R64) has already been characterised³, and was used at 1:400 dilution. Protein A-gold solution prepared according to the method of Roth *et al.*⁴ was used at a 1:15 dilution. In some experiments the same thin section was successively incubated with 15K and R64 antisera before exposure to the pAg solution. Thin sections were examined in a Philips EM 301 electron microscope.

The specific secretory granules of the human pancreatic A cell following glutaraldehyde and osmium tetroxide fixation and uranyl and lead staining appear as roundish, membrane-limited vesicles with a non-homogeneous content. Characteristically, the content is formed by a round, electron-dense core surrounded by a mantle of less electron-dense material⁵. This typical morphology is preserved by the glutaraldehyde fixation

Fig. 1 Three different thin sections showing two human α granules (in near-equatorial section) stained with the pAg technique using 15K anti-glucagon (*a*), R64 anti-glicentin (*b*) and anti-glucagon followed by anti-glicentin (*c*) sera, respectively. All sections were contrasted with uranyl acetate and lead citrate. With the anti-glucagon serum (*a*), the gold particles revealing the site of antiserum binding on glucagon antigens are situated mostly over the roundish, slightly eccentric, electron-dense core of the α granule. The anti-glicentin serum (*b*) binds gold particles almost exclusively over the paler, peripheral mantle of the granule surrounding the dense core. The third granule profile appearing at the lower margin of *b* represents a tangential section through the granule core and shows little gold binding. The three gold particles to the right are interpreted as mantle binding; mantle also appears blurred due to tangential sectioning. The successive incubation with anti-glucagon and anti-glicentin sera (*c*) shows a homogeneous binding of gold particles over the entire surface of the granule. The deposit of gold particles at the lower margin of *c* represents the staining of a tangentially cut (and thus not readily discernible) α granule mantle (compare with *b*). *a*–*c*, $\times 64,000$.

alone used for the pAg technique. In sections incubated with the C-terminal anti-glucagon serum, the gold particles revealing the glucagon antigenic sites seemed to be mostly restricted to the dense core of the α granule (Fig. 1*a*). With the anti-glicentin serum, gold particles were seen mostly on the peripheral mantle (Fig. 1*b*). A quantitative evaluation of the labelling induced by each antiserum on 100 granules showing both the dense core and the mantle in each condition showed approximately 77% of gold particles located over the core in glucagon-immunostained sections and 77% of the particles over the mantle in glicentin-immunostained sections. In sections incubated successively with both specific antisera, approximately equal numbers of gold particles were associated with the dense core and with the mantle of the 100 granules evaluated in this condition (Fig. 1*c*). This labelling pattern was consistently obtained in several experiments with different sections and different blocks of tissue. Control experiments omitting the antiserum step or

carried out with an antiserum absorbed with its corresponding antigen before application of the pAg solution showed only occasional gold particles over some α granules.

Although the presence of glucagon and glicentin immunoreactive material was demonstrated previously in the secretory granules of the A cell by the peroxidase-anti-peroxidase technique of Sternberger⁶ using anti-glucagon and anti-glicentin sera³, a detailed analysis of the localisation of these antigens was not possible due to the masking effect of the dense, irregular deposits of peroxidase reaction product. With the much improved resolution of the pAg technique, glucagon and glicentin immunoreactivity seem not to be mixed in the secretory granule, at least as judged by morphological criteria. In favour of the specificity of mantle labelling following application of anti-glicentin serum is the former cytochemical demonstration that Grimelius' silver preferentially stains the mantle (and not the core) of the α granule⁷, as well as the entire secretory granule content in the L cell⁸, the specific glicentin-producing cell of the intestine³. Although the mechanism(s) by which glucagon and glicentin immunoreactive material are packed and maintained separately in the α granule is unknown, the apparent segregation of these two polypeptides offers a reasonable explanation

of the previously puzzling inhomogeneity of the α granule content. That the dual granule content is co-secreted during α granule release is indicated by recent evidence showing efflux of glicentin-like immunoreactivity by the perfused porcine pancreas (J. J. Holst, S. Lindkaer and A. J. Moody, unpublished data).

This work was supported by grant no. 3.120.77 from the Swiss NSF. We thank Dr A. Perrelet for advice in writing the manuscript, Dr J. Roth for preparing the protein A-gold complex and G. Perrelet, I. Bernard and M. Sidler for technical assistance. 15K antiserum was supplied by Dr R. H. Unger, and R64 antiserum by Dr A. J. Moody (Novo).

Metastatic potential correlates with enzymatic degradation of basement membrane collagen

L. A. Liotta*, K. Tryggvason†, S. Garbisa*, Ian Hart†, C. M. Foltz§ & S. Shafie*

*Laboratory of Pathophysiology and †Fredrick Cancer Research Center, National Cancer Institute; ‡Laboratory of Developmental Biology and Anomalies, National Institute of Dental Research; §Laboratory of Chemistry, National Institute of Arthritis, Metabolism and Digestive Diseases, National Institutes of Health, Bethesda, Maryland 20205

Tumour cells traverse epithelial and endothelial basement membranes during the successive stages of the metastatic process. At the transition from *in situ* to invasive carcinoma, local dissolution of the basement membrane is observed microscopically^{1,2}, and coincides with tumour cell invasion of the underlying stroma. Tumour cells further traverse the endothelial basement membrane during entry into and egress from blood vessels³⁻⁵. Electron microscopy studies have shown local dissolution of basement membrane at its area of contact with invading tumour cells, suggesting an enzymatic mechanism^{3,6,7}. Basement membranes are resilient structures which present a mechanical barrier to invasion⁸. Type IV collagen is a major structural protein of basement membranes and is chemically and genetically distinct from stroma collagen types I and III and cartilage collagen type II^{9,10}. Previously characterised animal collagenases which cleave collagen types I, II and III fail to degrade type IV collagen^{11,12}. We have recently purified about 1,000-fold and characterised a neutral protease activity preferential for type IV collagen from metastatic tumour cells and shown that it (1) produces specific degradation products, (2) has a molecular weight of 65,000, (3) is not plasmin or a cathepsin, by pH and inhibitor studies, and (4) does not significantly degrade other collagens or fibronectin^{12,13}. Here we extend the relevance of this finding by quantitating the ability of several murine tumour cell lines of known metastatic potential to degrade type IV collagen. The cell lines with the highest incidence of spontaneous metastasis exhibit the greatest level of type IV collagen-degrading activity in two different assays using either living cells or media obtained from cell cultures.

The metastatic murine tumour cell lines used here were variants of the B16 melanoma and the T241 sarcoma. Cell lines F₁ and F₁₀ selected from the B16 melanoma exhibit a 10-fold difference in metastatic efficiency^{14,15} (number of lung colonies

per cell following tail vein injection). Line B16-BL6 is a variant with increased invasive capacity *in vitro* and *in vivo* selected from F₁₀ by injecting these tumour cells *in vivo* into the mouse bladder via the vas deferens. The bladder was then excised and cultured in 0.5% soft agar. Colonies in the agar that arose from cells which had invaded the bladder wall were collected and plated in Dulbecco's modified Eagle's medium and 10% fetal calf serum (FCS). When sufficient numbers of cells had grown in culture, they were cycled back through the bladder a total of six times (G. Poste, I. Hart and I. J. Fidler, in preparation). Line

Fig. 1 Basement membrane collagen-degrading activity in culture media from metastatic cell lines. Tumour cells and control cells were grown to log phase in T75 tissue culture flasks. Human polymorphonuclear leukocytes were isolated from the blood of normal volunteers by the Ficoll-Hypaque method, followed by dextran sedimentation and hypotonic lysis to remove erythrocytes. The leukocytes were suspended in Hank's balanced salt solution at a concentration of 4×10^6 cells per ml, and were incubated at 37 °C. Thirty minutes after the addition of FMLP chemotactic peptide, the cells were separated from the medium by centrifugation. The supernatant was assayed for type IV collagen degrading activity. As previously shown¹², 25-50% saturation of ammonium sulphate precipitates virtually all the enzyme activity. The precipitate was dissolved in and dialysed against the reaction buffer (0.05 M Tris-HCl, 0.2 mM NaCl, 10 mM CaCl₂, pH 7.6) in such a volume that it became 20 ml per 10^6 viable cells to assess direct comparison between cell number in original cultures. The reaction was preceded by trypsin activation of the enzyme by 0.25 volumes of trypsin ($10 \mu\text{g ml}^{-1}$) at 37 °C for 4 min followed by trypsin inhibition by 0.25 volume of soybean trypsin inhibitor ($50 \mu\text{g ml}^{-1}$). The enzyme reaction was carried out with various volumes of the activated enzyme at 37 °C for 4 h in a final volume of 1.6 ml containing 50 μl (2,500 c.p.m.) of ¹⁴C-proline-labelled type IV collagen in the reaction buffer. The undigested substrate was precipitated with 200 μl of a solution of 10% trichloroacetic acid and 0.5% tannic acid using 20 μl of bovine serum albumin (1 mg ml⁻¹) as a carrier. After precipitation at 4 °C for 30 min the tubes were spun at 2,500 r.p.m. for 15 min and aliquots of the supernatant were counted in a liquid scintillation counter. Enzyme activity is expressed as radioactivity (c.p.m.) released from substrate per μl of activated enzyme. The relative activity of the cell lines computed from the linear portion of the dilution curve is shown in Table 2. Maximum activity (100% in Fig. 1) is the number of counts released by bacterial collagenase. Trypsin digestions were used to control for any nonspecific protease activity in the samples. Trypsin ($0.5 \mu\text{g ml}^{-1}$) digested 14.0% of the substrate.

Table 1 Degradation of ^{14}C -proline-labelled basement membrane collagen by living cells

Cell type	Type IV collagen degradation (c.p.m. per 10^5 cells)	Incidence of spontaneous lung metastases*	Median (range) no. of pulmonary metastases following tail vein injection (5×10^4 cells) ($n = 10$)
Adult mouse fibroblasts	No detectable activity	None	None
Tumorigenic but non-metastatic transformed fibroblasts	No detectable activity	None	None
Cornea fibroblasts	No detectable activity	None	None
F ₁	35.0 \pm 11.0	None	13 (2-48)
F ₁₀	82.1 \pm 9.0	30% (within 4 weeks)	500 (170-500)
BL6	152.9 \pm 15.5	80% (within 4 weeks)	163 (43-264)
PMT	329.7 \pm 38.0	100% (within 2 weeks)	172 (82-310)

Costar tissue culture cluster wells were coated with ^{14}C -proline-labelled type IV collagen by applying 0.2 ml (2.5×10^3 c.p.m.) of a solution of the collagen in 0.01 M acetic acid to each well followed by evaporation. Cells in log phase of growth were collected by 0.1% EDTA with 80% viability and first washed with complete medium (RPMI-1640 + 10% FCS) and then with serum-free medium. Cell viability was judged by trypan blue exclusion. From 1×10^3 to 3×10^6 viable cells were inoculated into coated wells in a volume of 2 ml serum-free medium. After 10 h 1 ml of medium from each well was collected, centrifuged at 2,000 r.p.m. for 10 min at 4 °C and soluble radioactive digestion products were counted in a scintillation counter. Values shown are based on cell dose-dependent determinations and are related to the number of viable cells. The enzymatic activity is compared with the ability of these cells to form metastases. Both spontaneous lung metastases (derived from the transplanted tumour) and artificially induced lung metastases were studied. Note that the relative activity of the cell lines parallels the spontaneous metastatic properties more closely than the intravenous metastatic assay. Culture medium alone released 45 ± 20 ^{14}C c.p.m. per well or approximately 2.0% of applied counts. Purified bacterial collagenase (10 units) released $2,200 \pm 50$ c.p.m. or 90% of applied counts. Type IV collagen degradation was linear with time over the first 20 h. If soluble counts in an assay did not exceed counts released by culture media alone, the result was scored as no detectable activity.

* After intramuscular injection of 25,000 cells and amputation of the primary tumour ($n = 20$).

PMT was selected from a pulmonary metastasis of the T241 sarcoma as described previously¹⁶. Cell strains ACT and TACT are normal and spontaneously transformed adult mouse connective tissue cells, respectively, obtained by a method first described by Boone¹⁷. TACT cells are tumorigenic in 100% of mice but are non-metastatic.

Our first type of assay for type IV collagen-degradation activity consisted of inoculating living cells into tissue culture cluster wells coated with labelled substrate. The ^{14}C -proline-labelled type IV collagen used as substrate in our assays was prepared biosynthetically in organ cultures of a basement membrane-producing tumour (transplantable EHS sarcoma) from C57BL/6J mice. Methods for purification of the substrate have been described in detail previously^{18,19}. Cells in log growth phase were collected using 0.1% EDTA, and known numbers of viable cells were plated into each well. Degradation of the collagen layer resulted in the release of soluble counts into the medium which, for cells exhibiting activity, was verified in multiple assays to be proportional to the cell number. As shown in Table 1, the tumour cell lines exhibiting the highest activity *in vitro* also exhibited the highest propensity for spontaneous metastasis. However, this assay did not distinguish cell release of collagenase activity from cell phagocytosis of the substrate and intracellular digestion. We therefore searched for type IV collagenolytic activity secreted by these cells. Media from log phase cultures of these cell lines were collected and enzyme activity was precipitated from the media with 25-50% saturation of ammonium sulphate. The enzyme digestion consisted of

native ^{14}C -proline-labelled type IV collagen in solution incubated with trypsin-activated samples at pH 7.6 for 4 h. The undigested substrate was precipitated with 2.0% trichloroacetic acid and 0.08% tannic acid, and the digestion products were counted for radioactivity in the supernatant. This rapid assay for type IV collagenolytic activity, as elsewhere described^{12,13,20}, is highly reproducible. As shown in Fig. 1, the rate of the type IV collagenolytic activity was linear until about 60% of the substrate had been degraded. When the specific activity for each cell line was calculated from the linear portion of the concentration curves, the cell lines with the highest rate of spontaneous metastases *in vivo* exhibited the highest activity (Table 2).

The metastatic process is complex, involving many successive anatomic barriers which must be traversed by the malignant cell and many points where tumour cells can interact with host defences⁴. The ability to degrade basement membranes enzymatically may augment the aggressive behaviour of some metastatic cells. These cells may also differ from non-metastatic cells in other properties such as cell-surface proteins²¹. Furthermore, such an enzymatic activity is probably present in non-malignant cells in conditions where basement membrane is turned over¹². The metastatic tumour cell may exhibit a quantitative difference from normal cells in the synthesis of this enzyme and therefore measurement of its activity might serve as a biochemical marker *in vitro* for the metastatic potential of malignant cells.

We thank Karen Kniska for technical assistance. Bovine smooth muscle, endothelial and cornea cells were supplied by Dr Bert Glaser. We thank Dr G. R. Martin for discussions.

Received 16 August; accepted 26 November 1979.

Table 2 Basement membrane collagen-degrading activity secreted by cultured cells

Cell type	Type IV collagenolytic activity (c.p.m. per 2×10^5 cells)*
1. Mouse fibroblasts	None detected
2. Bovine aorta smooth muscle cells	None detected
3. Bovine cornea fibroblasts	None detected
4. TACT cells†	None detected
5. F ₁	398 \pm 36
6. F ₁₀	714 \pm 62
7. BL6	2,274 \pm 136
8. PMT	8,230 \pm 214
9. Bovine vein endothelium	56 \pm 27
10. Human leukocytes‡	880 \pm 90
11. Human leukocytes + chemotactic peptide‡	2,640 \pm 240
12. MCF-7 Human breast carcinoma cells	1,210 \pm 180

None detected: digestion in the assay was less than trypsin or media controls.

* Lines 1-8, $n = 10$; lines 9-11, $n = 5$. Mean \pm s.d.

† Tumorigenic but non-metastatic spontaneously transformed mouse connective tissue cells.

Terminal differentiation in human promyelocytic leukaemic cells in the absence of DNA synthesis

Giovanni Rovera, Nancy Olashaw & Pacifico Meo

The Wistar Institute of Anatomy and Biology, 36th Street at Spruce, Philadelphia, Pennsylvania 19104

Some phorbol diesters, the most potent of which is 12-O-tetradecanoylphorbol-13-acetate (TPA), exert two different effects on the differentiation of leukaemic cells *in vitro*: they reversibly inhibit the differentiation in Friend mouse erythroleukaemia cells^{1,2} and mouse myeloid leukaemia M1 cells³, and they induce differentiation in other mouse erythroleukaemia cells⁴, mouse myeloid leukaemia cells⁵, human promyelocytic leukaemia cells⁶⁻⁹ and cells of patients with myeloid and myelomonocytic leukaemia¹⁰. The effect on human leukaemic cells is both irreversible and independent of the continuous presence of the drug⁷. We report here that TPA-induced differentiation of human promyelocytic leukaemia cells (HL60) need not be preceded by a round of DNA synthesis, and that the majority of TPA-treated cells accumulate in the G1 phase of the cell cycle.

We and others have shown previously that TPA-treated HL60 cells 'terminally' differentiate into macrophage-like cells rather than mature myeloid cells^{5,7-9}. The evidence was based on either the appearance of markers in TPA-treated HL60 cells that are specific to the monocytic/macrophage lineage or the disappearance of myeloid markers. One monocytic marker is α -naphthyl acetate esterase (NAE), an enzyme which can be detected in the human bone marrow only in megakaryocytes or in monocytes¹¹; another is the presence of two acid phosphatase isozymes, 3a and 3b (ref. 12), which appear 3 d after TPA treatment⁹. Some myeloid markers, like myeloperoxidase and chloracetate esterase (CAE), are markedly reduced following TPA treatment of HL60 cells⁷. Markers common to both monocytic and myeloid cells, like phagocytosis, immunorethrophagocytosis, Fc receptors for immunoglobulin G, C3 receptors and lysozyme⁵⁻⁸ are also present after TPA treatment of HL60 cells. Although of little use in defining TPA-specific

differentiation, these markers are general indicators of differentiation. The present studies were designed to establish the relationship between the appearance of these differentiation markers and the cell cycle of TPA-treated HL60 cells. Four differentiation markers were used—NAE, CAE, acid phosphatase and its isozymes, and phagocytosis.

Figure 1 indicates that freshly plated, untreated HL60 cells, exponentially growing in culture, do not contain a sizeable fraction of cells in a resting state: continuous labelling with ³H-thymidine (TdR) for 48 h shows that 99% of the cells go through the S phase of the cell cycle at least once. Labelling of the cells for 1 h at the beginning of the experiment shows that about 48% of the exponentially growing cell population is at that time in S.

However, if TPA and ³H-TdR are added simultaneously to freshly plated HL60 cells, only a fraction of the cell population is labelled, even if the cells are exposed to the isotope for 72 h or more. This labelled fraction (52–55%) is only slightly in excess of that obtained by 1-h pulse labelling, which suggests that only a small fraction of the cells (~4–7%) which were not in S at the time of TPA addition are able to enter S after TPA treatment. Instead, most of the cells that were not in S (but in G2, M or G1) will never enter S after TPA treatment. The possibility that the lack of ³H-TdR incorporation in this subpopulation is a result of decreased TdR uptake, associated with normal cell proliferation, is ruled out as only a small increase in cell number is observed shortly after TPA treatment, and there is no increase at all after 12 h (ref. 7). As shown in Table 1, essentially all the TPA-treated cells became intensely positive for NAE (72 h after treatment), and CAE activity disappeared. Acid phosphatase was positive in almost all TPA-treated cells, and analysis of acid phosphatase isozymes by acrylamide gel electrophoresis confirmed that the monocytic-specific bands, 3a and 3b (ref. 9), were induced (not shown). Because about 48% of the TPA-treated cells never entered the S phase, it is clear that acid phosphatase and NAE could be expressed in TPA-treated cells

Fig. 1 HL60 cells^{16,17} were grown and induced to differentiate with 1.6×10^{-8} MTPA, as previously described⁷. TPA-treated and untreated cells were continuously labelled with ³H-TdR (0.1 μ Ci ml⁻¹; 6.7 Ci mmol⁻¹), collected by cytocentrifugation at the times indicated in the text and the figure, and processed for autoradiography¹⁵. Percentage of labelled cells are plotted against hours after addition of ³H-TdR. The cumulative percentage of labelled cells was determined at the time indicated. TPA and ³H-TdR were added to the treated cells simultaneously. ●, Untreated cells; ○, TPA-treated cells. Values represent the averages of two different experiments.

Table 1 Percentage of HL60 cells expressing differentiation markers

Experimental conditions	NAE	CAE	AcPh	Phagocytosis	
				³ H-labelled	Unlabelled
Untreated	1	80	9	3	2
TPA-treated	99	4	88	42	40

Cells were collected 72 h after TPA treatment and assayed for α -naphthyl acetate esterase (NAE), naphthol-AS-D chloroacetate esterase (CAE), acid phosphatase (AcPh) and phagocytic activity. A minimum of 500 cells was scored by two independent observers. Values represent averages of duplicate experiments; phagocytosis was scored in conjunction with autoradiography of ³H-TdR-labelled cells to determine whether cells bypassing the S phase developed phagocytic activity. Assay procedures are described in refs 7, 9 and 10.

without the cells undergoing a new round of DNA synthesis. We can also rule out the possibility that these marker enzymes are expressed constitutively in G1 because at any given time, 40–50% of the untreated cells were in G1 (see Fig. 2) but only 1% were positive for NAE and 10% were positive for acid phosphatase (Table 1).

Phagocytic activity was assayed in TPA-treated cells labelled continuously with ³H-TdR for 3 days. Following autoradiography, positive and negative cells were scored for both acid-insoluble radioactivity in the nucleus and the presence of latex beads in the cytoplasm (Table 1). Both the cell populations that went through S and those that did not develop phagocytic capability.

From these experiments, we concluded that transition through the S phase was not required for differentiation of TPA-treated HL60 cells into macrophage-like cells. It was still not clear, however, whether TPA treatment caused cells to stop in different phases of the cell cycle (an indication of a toxic effect on the cells) or in one particular phase. To answer this question, we pulse labelled (1 h) HL60 cells with ³H-TdR at different

Fig. 2 Percentage of cells plotted against DNA content in arbitrary units. *a* Represents the distribution of DNA content in TPA-treated HL60 cells, and *b*, the distribution of DNA content in untreated HL60 cells. Numbers in the upper right corners indicate hours after plating the cells with or without TPA. HL60 cells have a modal chromosome number of 44 (refs 16, 17). The DNA content of a minimum of 200 cells per time point was determined with a Vickers M85 scanning microdensitometer after Feulgen staining. A standard was obtained by blocking the cells in S phase with fluorodeoxyuridine.

times after the addition of TPA and determined the percentage of cells that incorporated ^3H -TdR into their DNA (Fig. 3). This percentage was found to decrease progressively after TPA treatment. As this result could be interpreted as either a decreasing number of cells in S and normal TdR uptake, or a constant number of cells in S and decreasing TdR uptake, we determined the DNA content in each cell at different times after TPA treatment. The results shown in Fig. 2 indicate that the population of cells in S did, in fact, progressively decrease. The DNA distribution of untreated HL60 cells at different times after seeding was relatively constant: approximately 52% of the cells had a G1-level DNA content, 8% had a G2-level content, and 40% an S-level intermediate content. Following TPA treatment, there is a progressive decrease in the fraction of cells

Fig. 3 Percentage of labelled cells plotted against hours after the beginning of the experiment. HL60 cells, either untreated (●) or treated (○) with 1.6×10^{-8} M TPA were pulse labelled for 1 h with ^3H -TdR ($0.1 \mu\text{Ci ml}^{-1}$) at different times after the beginning of the experiment. Values represent the averages of two different experiments.

Fig. 4 Cell cycle model for TPA-induced differentiation of HL60 cells. R: point late in G1 beyond which TPA-treated cells may still proceed through one cell cycle. A, B, C, D, Fate of cells in S, G2, M and G1, respectively, at the time of TPA treatment.

with an S-phase DNA content, and an increase in the fraction of cells with a G1 DNA content. Eighty per cent of the cells were found to be G1 72 h after TPA treatment.

These results indicate that TPA-treated HL60 cells accumulate in G1 rather than stopping at various phases of the cell cycle. We have shown previously that the arrested cell cannot be restimulated to proliferate by changing the medium or by removing the TPA⁷. Rather, the cells remain quiescent until their death, 4 to 6 days after the addition of TPA.

The data presented here suggest the model of the TPA effect on the cycle of HL60 cells that is shown in Fig. 4. There is a stage, R, late in G1, after which TPA-treated cells will proceed through S, complete the cycle, stop in G1 and differentiate. Cells in G2, M or early-to-middle G1 at the time of TPA treatment will stop in G1 and differentiate without requiring new DNA synthesis.

The process of TPA-induced differentiation of HL60 cells into macrophage-like cells is rapid and lacks the multiple cell divisions normally associated with the transition from a promyelocytic to a more differentiated myeloid cell. Thus, TPA-induced differentiation differs from known *in vivo* and *in vitro* models of erythroid and myeloid differentiation. However, little is known about monocytic differentiation. It is generally accepted that monocytes and myeloid cells have a common progenitor¹³, and there is evidence for the extremely rapid *in vivo* formation of monocytes from precursors in the mouse¹⁴. Therefore, it is possible that TPA-induced differentiation *in vitro* may not be totally anomalous, but could mimic some *in vivo* process. Because TPA can force myeloid cells in every phase of the cell cycle to become irreversibly quiescent, this drug and others with a similar effect, such as mezerein⁸, may be useful as anti-leukaemic agents in experimental models^{5,6,8}.

Phorbol ester-mediated stimulation of the synthesis of mouse mammary tumour virus

S. K. Arya

Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205

12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) is a potent tumour promoter in the two-stage mouse skin carcinogenesis model^{1,2}. Recently, TPA has been shown to enhance the transformation of cultured cells by two DNA tumour viruses—adenovirus³ and Epstein-Barr virus⁴. It is not known whether TPA also augments the transformation of cells by RNA tumour viruses. In Rous sarcoma virus (type C) transformed fibroblasts, the levels of plasminogen activator are elevated by TPA^{5,6}, a phenomenon also associated with malignant transformation^{7,8}. In addition, TPA and other promoters induce the synthesis of some herpesviruses in persistently infected cells^{9,10}. I have investigated the effect of TPA on the synthesis of mouse mammary tumour virus (MMTV), type B RNA tumour virus, and find that TPA, in nanogramme quantities, causes a 10- to 20-fold stimulation of MMTV production by persistently infected mouse mammary tumour cells. This stimulation is specific for TPA; the non-promoter, phorbol, does not stimulate MMTV production.

Fig. 1 Effects of TPA on cell growth (a) and virus production (b) by mouse mammary tumour cells grown in the absence of dexamethasone. Duplicate monolayer cultures of Mm5mt/c₁ cells were treated with TPA for 48 h. Twenty-four hours before collecting medium, cultures were given fresh medium with or without TPA. Samples of medium (18–20 ml per culture) were clarified and centrifuged at 25,000 r.p.m. for 90 min at 4°C in a Beckman SW 27.1 rotor. The pellet was suspended in 0.01 M Tris-HCl (pH 7.8)/0.1 M NaCl/1 mM EDTA (TNE), layered on a column of 20% glycerol in TNE, and centrifuged at 35,000 r.p.m. for 60 min at 4°C in a Beckman SW 50.1 rotor. The pellet was dissolved in 100–200 µl of 0.01 M Tris-HCl (pH 7.8)–0.01 M NaCl and 20–40 µl aliquots were used for virus estimation by particle-associated RNA-directed DNA polymerase assay. The polymerase assays utilizing poly(C): oligo(dG) as a template: primer and magnesium ion as a cofactor were performed as described before^{13,14}. The data in (a) show the number of cells per culture and in (b) show the amount of ³H-labelled dGMP (3,500 c.p.m. pmol⁻¹) incorporated into acid insoluble material by purified particle preparation corresponding to 1 ml of collected medium.

Fig. 2 Effect of TPA (○) and phorbol (■) on cell growth (a) and virus production (b) by mouse mammary tumour cells grown in the presence of dexamethasone (2 µg ml⁻¹). Experimental details as for Fig. 1, except the specific activity of ³H-dGTP used for polymerase assays was 700 c.p.m. pmol⁻¹. The data in (c) show the ratio of magnesium (20 mM) over manganese (1 mM) cofactored DNA polymerase activity of purified particle preparations.

MMTV producing C3H mouse mammary tumour derived cells, designated Mm5mt/c₁ (refs 11, 12), were treated with TPA for 48 h in the presence or absence of dexamethasone. Figure 1 shows the effect of TPA on virus production when the cells were grown in medium without dexamethasone. Clearly, TPA markedly enhanced virus production without significantly affecting cell growth. The effect was dose-dependent: at 1 ng ml⁻¹, the virus production was stimulated by about 8-fold; at 10 ng ml⁻¹, the stimulation was nearly 20-fold. The increased virus production could not be ascribed to the induction of endogenous type C virus(es). The particle-associated DNA polymerase of MMTV prefers magnesium ions as cofactor while that of type C viruses prefers manganese ions^{13,14}. Thus the ratio of polymerase activity in the presence of magnesium and manganese ions is characteristic of the virus type. In our case, TPA did not change this ratio in ways suggesting the induction of type C virus(es) (see Fig. 2c). As dexamethasone also enhances the synthesis of MMTV^{12,15,16}, we determined whether TPA would act synergistically with dexamethasone. As shown in Fig. 2, TPA stimulated virus production even when the cells were grown in the presence of dexamethasone (2 µg ml⁻¹). Again the effect was dose-dependent. The maximum stimulatory effect of 10- to 12-fold was obtained at a TPA concentration of 10 to 20 ng ml⁻¹. As dexamethasone alone stimulated virus production 10- to 20-fold the combined effect of dexamethasone and TPA apparently resulted in 100- to 200-fold enhancement of virus production. This effect was specific for TPA; the non-tumour promoter, phorbol, failed to stimulate virus production up to a concentration of 100 ng ml⁻¹ (Fig. 2).

The effect of TPA on the steady state level of intracellular viral RNA was also examined. This was done by hybridising cellular RNA with representative MMTV complementary DNA (cDNA). The cDNA was prepared by transcribing 30–35S viral RNA with avian myeloblastosis virus reverse transcriptase in the presence of calf thymus DNA oligomers¹⁷. The cDNA contained a uniform representation of 75–80% of viral sequences; other sequences were less frequently represented

Fig. 3 Effect of TPA on the steady state level of intracellular viral RNA in mouse mammary tumour cells grown in the presence and absence of dexamethasone. Cellular RNA was isolated by phenol extraction and DNase digestion. A solution of RNA ($0.5\text{--}1\text{ mg ml}^{-1}$) and cDNA ($20,000\text{ c.p.m.}$ or 1 ng ml^{-1}) in $0.3\text{ M NaCl}/0.03\text{ M Na citrate } 2\text{ mM EDTA } 0.02\%$ sodium lauryl sarcosinate ($\text{pH } 7$) was incubated at 65°C . Aliquots were withdrawn at intervals and hybrids were scored by S_1 nuclease digestion. The R_0t [concentration of RNA (mol l^{-1}) \times time (s)] values have been reduced to standard conditions of 0.18 M NaCl and 60°C ¹⁸. The curves represent cellular RNA from untreated cultures (Δ), cellular RNA from TPA-treated (20 ng ml^{-1}) cultures (\blacktriangle), cellular RNA from dexamethasone-treated ($2\text{ }\mu\text{g ml}^{-1}$) culture (\circ), cellular RNA from cultures treated with dexamethasone ($2\text{ }\mu\text{g ml}^{-1}$) plus TPA (20 ng ml^{-1}) (\bullet), MMTV RNA (\blacksquare), murine leukaemia virus (AKR) RNA (\blacklozenge), and yeast RNA (\square).

(data not shown). The MMTV cDNA did not hybridise with murine leukaemia virus (AKR) RNA (Fig. 3). Conversely, the cDNA of murine leukaemia virus (AKR) did not hybridise with MMTV RNA. Thus MMTV cDNA contained only MMTV specific sequences. The R_0t analyses revealed that TPA (20 ng ml^{-1}) increased the concentration of intracellular MMTV specific RNA 5- to 7-fold relative to control cultures (Fig. 3). Dexamethasone ($2\text{ }\mu\text{g ml}^{-1}$) alone caused a 6- to 7-fold increase in the concentration of intracellular viral RNA and this was increased a further 5-fold by TPA (20 ng ml^{-1}). These results suggest that TPA causes an increase in the transcription of viral RNA accompanied by a stimulation of assembly and release of virus particles. Note that the magnitude of TPA-caused enhancement of intracellular viral RNA does not strictly correspond to its effect on extracellular virus production. At a TPA concentration of 20 ng ml^{-1} , the level of intracellular viral RNA was increased 5- to 7-fold while extracellular virus production was enhanced 15- to 20-fold. Further, it is not yet known whether TPA directly affects some activity specific for virus synthesis or whether its effect is mediated through some cellular function. The effect of TPA seems to be specific for the synthesis of MMTV; TPA, up to 100 ng ml^{-1} , did not enhance the production of type C virus(es) by late passage Mm5mt/c₁ cells. The biological significance of these results in terms of mammary tumour development in whole animals remains to be ascertained.

Sister chromatid exchange in cells metabolically coupled to Bloom's syndrome cells

Steven Schonberg & James German

Cornell University Graduate School of Medical Sciences and The New York Blood Center, New York, New York 10021

Cells from persons with Bloom's syndrome (BS) show many more sister chromatid exchanges (SCEs) than cells from normal individuals or those with any other genetic disease studied so far¹. Several other abnormalities demonstrable in cell culture (reviewed in ref. 2) suggest that the molecular defect in BS is related to DNA metabolism; for example, many chromosomal aberrations in untreated cells³, abnormally slow DNA chain growth^{4,5}, and increased sensitivity to treatment with ethyl methanesulphonate^{6,7}. BS cells respond as normal cells do in excision repair⁸⁻¹⁰, 'post-replication repair'¹¹, and repair of single-strand breaks¹². This apparent proficiency at repair prompted the suggestion^{13,14} that the various chromosome abnormalities result from an excessive accumulation spontaneously of lesions in the DNA on which a repair system(s) must act, thereby overloading the system(s). Such lesions might result, for example, from the action of a genetically defective enzyme involved in the semi-conservative replication of DNA, a defect leading to a quantitative imbalance in a chromosomal component, or a defect leading to the intrinsic production of a molecule with mutagenic properties. Experiments designed to test this last possibility have resulted in conflicting reports¹⁵⁻¹⁸. We report here results which do not support the hypothesis that BS cells release such a mutagenic molecule. SCE frequencies in non-BS cells were not affected when the cells were placed in contact-dependent metabolic coupling with BS cells. Also, when we repeated experiments¹⁵ in which medium 'conditioned' by BS fibroblasts was reported to increase the amount of SCE in normal blood lymphocytes, we were unable to duplicate those results.

Lesch-Nyhan syndrome fibroblasts, deficient in hypoxanthine guanine phosphoribosyltransferase (HGPRT⁻ cells), were co-cultivated with BS fibroblasts in hypoxanthine, aminopterin and thymidine (HAT)¹⁹ selective medium. In such conditions, the only HGPRT⁻ cells to proliferate are those metabolically coupled to BS cells²⁰, presumably due to the free exchange of nucleotides through gap junctions²¹. Pairs of cell lines used were opposite in sex—HGPRT⁻ male and BS female. After 3 d of co-cultivation, metaphase chromosome preparations were made. Chromosomes were stained with quinacrine and studied by fluorescence microscopy to determine the presence or absence in each metaphase of a Y chromosome. The chromosomes were then stained to give sister chromatid differentiation, and SCEs were counted. Both experimental and control co-cultivations were performed twice (Table 1, experiments 1 and 2); different lines of HGPRT⁻, BS and normal cells

Table 1 Effect of co-cultivation on SCE frequencies in HGPRT⁻, BS and normal fibroblasts

Cell line(s) in culture		HGPRT ⁻ cells		SCE per cell BS cells		N cells	
Component A	Component B	$\bar{x} \pm \text{s.e.m.}$	Range	$\bar{x} \pm \text{s.e.m.}$	Range	$\bar{x} \pm \text{s.e.m.}$	Range
Experiment 1							
HGPRT ⁻ 1		8.7 \pm 0.5	3-14 (30)				
HGPRT ⁻ 1*		9.3 \pm 0.8	4-17 (24)				
	BS 1			60.0 \pm 2.0	32-80 (30)		
	N 1					10.1 \pm 0.8	3-20 (30)
HGPRT ⁻ 1 + BS 1		10.0 \pm 0.7	5-18 (24)	58.8 \pm 3.1	33-95 (19)

HGPRT ⁻ 2 + N 2		5.8 \pm 0.4	2-12 (26)			6.2 \pm 0.4	1-12 (59)

The fibroblast lines used were actively growing, between the 9th and 22nd *in vitro* passages. Trypsin was used in passaging (1:2 splits) and collection. The HGPRT⁻ cell lines were GM-1662 (referred to as HGPRT⁻ 1) and GM-1362 (HGPRT⁻ 2) obtained from the Human Genetic Mutant Cell Repository at Camden. The BS cell lines were HG 916 (BS 1) and HG 369 (BS 2) derived in this laboratory from skin biopsies taken from patients identified in the Bloom's Syndrome Registry²⁶ as, respectively, 53(StAs) and 26(SaTi). The normal control fibroblast lines (referred to as N in these tables), also derived from skin biopsies taken here, were HG 883 (N 1) and HG 846 (N 2). All co-cultivations were initiated at 1:1 cell ratios. Medium was Eagle's minimal essential medium (MEM) with 10% fetal bovine serum (FBS), penicillin (50 U ml⁻¹), and streptomycin (50 µg ml⁻¹). All medium, except that used for cultures of HGPRT⁻ cells alone, was supplemented with hypoxanthine (2×10^{-2} M), aminopterin (0.8×10^{-4} M) and thymidine (3.2×10^{-3} M) (HAT medium). Cultures were gassed with a mixture of 10% CO₂ in air and stoppered. Initial cell seeding for all cultures was at 3.5×10^5 cells per 8-ounce glass flask. Twenty-four hours after seeding, cells were provided with fresh medium to which 10 µM BrdU had been added. Thereafter, cultures were incubated in the dark until metaphase preparations were made 48 h later by standard techniques. Metaphases from cultures containing two cell lines were stained with quinacrine and studied by fluorescence microscopy. The locations of all diploid metaphases with good morphology were recorded (cells with 43 or fewer chromosomes being rejected) and each metaphase was classified as to the presence or absence of a Y chromosome. Slides were then rinsed in demineralised water and dried overnight. On the following day, the metaphases were stained for sister chromatid differentiation with Giemsa stain, as described previously²⁷. Metaphases previously identified by fluorescence were relocated on the slides and studied for SCEs. SCEs were counted in metaphase cells which had gone through two rounds of DNA replication in the presence of BrdU and which showed good quality sister chromatid differential staining. Metaphases from cultures containing one cell line were stained for sister chromatid differentiation, and SCEs were counted in up to 30 consecutive cells meeting the criteria described above. SCE was determined for some cell lines several times during the course of the experiments, indicated by an asterisk. Numbers of cells analysed are shown in parentheses.

were used in the two sets of experiments. As Table 1 shows, HGPRT⁻ cells in metabolic coupling to BS cells for two cell cycles maintained their normal numbers of SCEs, and they had no effect on SCE in the BS cells.

To determine whether the experimental system had any effect on the amount of SCE present, both lines of HGPRT⁻ cells were co-cultivated in HAT medium with fibroblasts from normal females. The amount of SCE did not differ between co-cultivated and control HGPRT⁻ or normal female cells (Table 1). The HAT medium itself had no effect on SCE in either BS or normal fibroblasts (data not shown).

Published data¹⁵ indicate that medium conditioned by a line of BS fibroblasts increased SCE in phytohaemagglutinin (PHA)-stimulated blood lymphocytes from a normal individual. We repeated that experiment, using 'conditioned' medium from the same BS fibroblast line; also tested were media from two other BS lines and two lines of normal fibroblasts. Medium 'conditioned' by neither BS nor normal fibroblasts affected SCE in the blood lymphocytes of two normal individuals (Table 2).

Data from other laboratories¹⁶⁻¹⁸ indicate that the amount of SCE is reduced in BS fibroblasts in various conditions of co-cultivation, the size of the decrease depending on the initial proportions of cells used. While it is noteworthy that we observed no such effect, the altered metabolism of the non-coupled HGPRT⁻ cells in HAT medium may have precluded it. Thus, while the data presented here do not confirm the reports just cited¹⁶⁻¹⁸, further investigation, designed specifically to study that particular issue, will be required.

Bryant *et al.*²² reported experiments in which cell hybrids between diploid BS and diploid normal fibroblasts were produced; the hybrid cells had the low amount of SCE characteristic of the normal parental cells. With respect to the representation in their genomes of the BS gene, the hybrid cells are the equivalent of tetraploid cells occasionally found in cultures from BS heterozygotes, which have normal numbers of SCEs (our unpublished observations) as do diploid cells from BS heterozygotes^{1,23}. As such, therefore, these hybrids²² give no insight as to whether BS cells produce a factor that can increase SCE in normal cells.

In our experiments (Table 1) every HGPRT⁻ cell showing sister chromatid differential staining was coupled metabolically to a BS cell(s) for two cycles of DNA replication, ensuring exchange of small molecules between the cells²¹. The molecular size limit for exchange through mammalian gap junctions is approximately 900 daltons²⁴, a limit which encompasses essentially all mutagenic molecules currently recognised²⁵. We conclude that no such molecule was transferred from BS to HGPRT⁻ cells. Neither did our results support the idea that BS cells secrete a mutagen of greater than 900 daltons into the culture medium to be taken up by non-BS cells.

We thank Dr R. Tice for providing necessary information to repeat his experiment. This research was supported in part by grants from NIH (HD 04134 and HL 09011) and the American Cancer Society. S.S. was supported by NIH predoctoral training grant 5T01GM01918-06.

Table 2 The effect on SCE in normal lymphocytes of medium 'conditioned' by BS fibroblasts

Source of medium	SCE in normal lymphocytes			
	Blood no. 1		Blood no. 2	
	$\bar{x} \pm \text{s.e.m.}$	Range	$\bar{x} \pm \text{s.e.m.}$	Range
Control	9.0 \pm 0.6	2-18 (50)	8.4 \pm 0.5	4-19 (50)
N 1	8.2 \pm 1.0	3-12 (12)	7.9 \pm 0.4	2-12 (50)
N 3	9.2 \pm 0.5	4-25 (50)	8.0 \pm 0.6	1-20 (50)
BS 1	9.4 \pm 0.5	2-16 (50)	7.2 \pm 0.5	2-16 (50)
BS 3	8.5 \pm 0.4	2-16 (50)	7.3 \pm 0.4	2-14 (50)
BS 4	10.4 \pm 0.7	2-17 (28)	8.4 \pm 0.5	4-20 (47)

PHA (Wellcome)-stimulated blood samples from two normal individuals were cultured in the dark in 5% CO₂ in Eagle's MEM supplemented with 15% FBS, 2 mM L-glutamine, penicillin (100 U ml⁻¹), streptomycin (100 µg ml⁻¹) and BrdU (25 µM). Forty hours after initiation, cultures handled in a dimly lit room were centrifuged at 1,000 r.p.m. for 8 min and half of the medium (5 ml) was replaced with either fibroblast-conditioned or control (not conditioned) medium prepared as described below. Cells were collected 24 h later for metaphase preparations by standard techniques. Staining for sister chromatid differentiation and criteria for cell selection were as for Table 1. Slides were coded, and SCEs were counted directly through the microscope ($\times 1,000$) in up to 50 consecutive metaphases. Fibroblast medium was as described for Table 4, experiment 2 of ref. 15 except that antibiotic concentrations were 100 U ml⁻¹ for penicillin and 100 µg ml⁻¹ for streptomycin. All fibroblast cultures were actively growing, between subculture passages 16 and 29 (1:2 splits). The final passage was by a 1:4 split, and 24 h later fibroblasts were rinsed with Earle's balanced salt solution and then provided with fresh medium. After further 4 d of incubation, medium was removed from nearly confluent cultures and centrifuged at 1,200 r.p.m. for 10 min to remove cellular debris. BrdU (25 µM) was added to both the conditioned media and the control medium, and these media were used immediately to replace half of the medium in the blood cultures. BS fibroblast lines used were HG 916 (BS 1), HG 1219 (BS 3) and GM-1492 (BS 4) from, respectively, 53(StAs), 81(MaGrou) and 44(AbRu). Control fibroblast lines were HG 883 (N 1) and HG 978 (N 3). Cell lines BS 1 and N 1 are the same as in Table 1. All cell lines were derived from skin biopsies taken in this laboratory, except GM-1492 which was obtained from the Human Genetic Mutant Cell Repository. Numbers of cells analysed are shown in parentheses.

Induction of sister chromatid exchanges by BUdR is largely independent of the BUdR content of DNA

Richard L. Davidson*, Elliot R. Kaufman*,

Division of Genetics and Mental Retardation Center, Children's Hospital Medical Center, and Departments of Microbiology and Molecular Genetics* and Pediatrics†, Harvard Medical School, Boston, Massachusetts 02115

The halogenated thymidine (dT) analogue, 5-bromodeoxyuridine (BUdR), has a variety of effects on mammalian cells, including toxicity, suppression of differentiation, and mutagenesis. Although it is generally assumed that the effects of BUdR are due primarily to its presence in DNA, results from our laboratory have raised doubts about such assumptions¹⁻⁴. We have shown, for example, that BUdR mutagenesis in mammalian cells is determined by the concentration of BUdR in the medium rather than in DNA³, and that mutagenesis can be suppressed by deoxycytidine (dC) without changing the amount of BUdR in DNA⁴. BUdR has also been shown to induce sister chromatid exchanges (SCEs) in mammalian cells⁵⁻⁷. Initial results suggested that the relationship between BUdR and SCEs might not be explained by a single factor⁵, and various correlations between BUdR and SCEs have been proposed^{8,9}. However, the results to date have been inconclusive, because the experiments did not resolve as independent variables the concentration of BUdR in the medium and the amount of BUdR incorporated into nuclear DNA. We have now carried out experiments to resolve these two factors; the results indicate that the major factor in determining the frequency of SCEs is the concentration of BUdR in the medium.

The cells used in these experiments were from a clone of Chinese hamster ovary (CHO) cells. The occurrence of SCEs was monitored by growing cells for two generations in the presence of BUdR and staining with the fluorescent bisbenzimidazole dye, 33258 Hoechst¹⁰, and Giemsa¹¹. In most experiments, the incorporation of BUdR into nuclear DNA and the induction of mutations by BUdR were measured in parallel cultures.

When CHO cells were grown in medium containing BUdR at concentrations ranging from 12 to 300 µM, the frequency of SCEs increased by over fourfold and the level of BUdR incorporation into DNA (BUdR substitution) also increased (Fig. 1a). To evaluate the role of the increased BUdR concentration *per se*, cells were grown in medium (FBT) containing 5-fluorodeoxyuridine (FudR, an inhibitor of *de novo* dT biosynthesis) plus BUdR and dT at varying concentrations but at a fixed ratio. When CHO cells were grown in FBT medium containing 12-300 µM BUdR and with the BUdR:dT ratio fixed at 3:2, the frequency of SCEs increased by over threefold (Fig. 1a). However, because of the presence of FudR and the fixed ratio of BUdR:dT, the level of BUdR substitution remained constant at approximately 60%. The increase in SCEs due to raising the BUdR concentration at a fixed level of BUdR substitution accounted for most of the increment in SCEs observed when the level of BUdR substitution was allowed to increase with the BUdR concentration. Similar data were obtained in several independent experiments. These results suggest that the major factor in determining the frequency of induction of SCEs is the concentration of BUdR in the medium rather than the amount of BUdR incorporated into DNA. The

Table 1 Induction of SCEs by BUdR

Medium additive (μ M)		BUdR substitution (%)	SCEs per cell	Mutant frequency
BUdRdT	dC			
Part 1: FUDR present				
12	24	38.8	7.5	<1
180	360	35.0	23.7	120
12	8	64.5	10.4	<1
180	120	59.1	22.6	214
12	2	85.0	12.9	<1
180	30	85.8	24.2	168
Part 2: FUDR present				
12	24	33.9	6.6	<1
12	8	64.5	9.3	<1
12	2	84.1	11.4	<1
12	—	95.1	14.4	NT
Part 3: FUDR absent				
12	—	75.8	8.7	<1
180	—	94.0	23.4	152
Part 4: FUDR present				
12	24	—	8.2	NT
12	24	200	7.9	NT
12	1	—	12.7	NT
12	1	200	13.3	NT

The analyses were carried out as described in Fig. 1 legend. The cells were exposed to BUdR in either FBT medium (FUDR present) or E medium (FUDR absent) with the indicated concentrations of BUdR, dT and dC. NT, Not tested.

induction of mutations by BUdR in CHO cells was also determined by the BUdR concentration in the medium (Fig. 1b), in agreement with the results of our previous studies with Syrian hamster cells³. The parallel between the induction of SCEs and mutations by BUdR agrees with the relationship previously proposed for SCEs and mutations induced by other agents¹².

The results in Fig. 1a showed that increasing the BUdR concentration while holding the level of BUdR substitution constant at 60% resulted in a large increase in the frequency of SCEs. The ratio of BUdR:dT in FBT medium was varied, and similar tests were carried out with the level of BUdR substitution fixed as low as 35% or as high as 85%. As shown in Table 1, part 1, the relationship between BUdR concentration and SCEs was observed over the entire range of BUdR substitution levels tested.

Experiments were carried out to determine whether increasing the level of BUdR substitution had an effect of its own on the induction of SCEs. CHO cells were grown in FBT medium with a fixed concentration of BUdR (12 μM), and the level of BUdR substitution was increased by decreasing the amount of dT in the medium. As shown in Table 1, part 2, increasing the BUdR substitution in this manner from 34% to 95% had only a small (approximately twofold) effect on the frequency of SCEs, although this effect was reproducible in independent experiments. These results suggest that the level of BUdR substitution has a minor role in determining the frequency of SCEs induced by BUdR. The relative roles of BUdR concentration and substitution in determining the frequency of SCEs can be judged by comparing the SCEs induced by 180 μM BUdR alone with those induced by FUDR plus 12 μM BUdR but without dT. Although the levels of BUdR substitution were the same in both conditions (~95%), the frequencies of SCEs were quite different (Table 1, parts 2 and 3). Clearly, the concentration of BUdR, not the level of BUdR substitution, was the major factor. Furthermore, as shown in Fig. 2, the ratio of exogenous BUdR molecules:cell number did not have a significant effect on the frequency of SCEs, in contrast to previous reports^{8,9}.

The results in Table 1, part 2, showed that increasing the level of BUdR substitution while maintaining the concentration of

**Fig. 1** Effect of BUdR concentration on the induction of SCEs.

For the determination of SCEs, tissue culture dishes (100 mm diameter) were inoculated with 5×10^5 CHO cells in 9 ml of Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum (E medium). After several hours at 36.5 °C, 1 ml E medium containing BUdR and other additives at 10 times the desired final concentration was added to each dish. After 36 h, colcemid ($0.06 \mu\text{g ml}^{-1}$) was added, the cells were collected 2 h later, stained with 33258 Hoechst dye¹⁰, exposed to visible light and stained with Giemsa as described previously¹¹. Each point represents the average frequency of SCEs per cell for at least 20 cells. For the determination of mutant frequencies, dishes (100 mm diameter) were inoculated with 1×10^5 cells in 9 ml E medium, and the cells were exposed to BUdR and other additives for 36 h as described above. After the exposure to BUdR, the cultures were rinsed twice and renewed with 20 ml E medium containing 0.1 mM hypoxanthine and 16 μM dT (HT medium). After 5 days growth in HT medium, to allow for the expression of any mutations induced, the cells were collected and dishes (150 mm diameter) were inoculated with 2×10^5 cells in E medium containing 18 μM 6-thioguanine (TG). Dishes (60 mm diameter) were also inoculated with 250 cells in E medium alone. After 7 days, the cultures were fixed and stained, and colonies with more than 50 cells were counted in triplicate dishes. The results are expressed as the number of TG^r colonies per 10^5 cells, after correcting for the plating efficiency of the cells in the absence of TG. For the determination of BUdR incorporation into DNA, dishes (150 mm diameter) were inoculated with 10^6 cells in 45 ml E medium. After several hours, 5 ml E medium containing BUdR and other additives at 10 times the desired final concentration was added. Twelve hours later, $2 \mu\text{Ci ml}^{-1}$ $\text{H}_3^{32}\text{PO}_4$ was added. After a further 36 h, the cells were collected, the DNA isolated and the base composition of the nuclear DNA determined as previously described¹⁷. Four determinations were made for each sample. The results are expressed as 'BUdR substitution', the percentage of dT residues in nuclear DNA replaced by BUdR. To avoid effects due to the photosensitivity of BUdR substituted DNA, the cells were protected at all times from wavelengths of light below 550 nm¹⁷. The cells were exposed either to BUdR alone (●) or to BUdR in the presence of 10 μM FUDR and dT (FBT medium) with the ratio of BUdR:dT fixed at 3:2 (○). The numbers by the data points indicate % BUdR substitution.

BUdR fixed had a small but apparently real effect on SCE induction. However, it can be seen that increasing the level of BUdR substitution in these conditions had no detectable effect on the induction of mutations. Thus, even though a reasonably good correlation between the induction of SCEs and mutations by BUdR was observed in most conditions (see Figs 1, 3), conditions exist in which the induction of SCEs and mutations by BUdR seem to be separable.

Because we had found that dC can suppress BUdR mutagenesis⁸, experiments were carried out to determine the effect of dC on BUdR-induced SCEs. These experiments were carried out in the presence of FUDR, to prevent the conversion of the exogenously supplied dC to dT nucleotides. As shown in

Fig. 3a, the addition of 200 μM dC largely suppressed the increase in SCEs due to increasing the BUdR concentration from 12 to 300 μM . Because of the presence of FUDR, this suppression occurred in the absence of changes in BUdR substitution. Comparable results were observed for the suppression of BUdR mutagenesis by dC (Fig. 3b), in agreement with previous results⁴.

Experiments were also carried out to test the ability of dC to suppress the induction of SCEs caused by increasing the level of BUdR substitution (from 35% to 88%) while maintaining a fixed concentration of BUdR (12 μM). In contrast to the results in Fig. 3a, dC had no effect on the induction of SCEs by BUdR in these conditions (Table 1, part 4). Thus, dC can suppress the induction of SCEs caused by increasing the concentration of BUdR, but apparently cannot suppress the induction of SCEs caused by increasing the level of BUdR substitution.

Fig. 2 Effect of BUdR:cell ratio on the induction of SCEs. The analyses were carried out as described in Fig. 1 legend. The cells were exposed to BUdR in FBT medium with a 3:2 ratio of BUdR:dT. At a given BUdR concentration, the different BUdR:cell ratios were generated by varying the ratio of the volume of culture medium to the number of cells. At 30 μM BUdR (●) and 60 μM BUdR (■), cultures were tested at 5×10^5 cells per 10 ml (left point) or 1×10^5 cells per 20 ml (right point). At 90 μM BUdR (▲), cultures were tested at 1×10^6 cells per 5 ml (left point) or 5×10^5 cells per 10 ml (right point).

As the BUdR plus dye technique is being used to screen compounds for SCE induction, experiments were carried out to determine whether the conditions of BUdR treatment could affect the induction of SCEs by other agents. Cells were grown in FBT medium such that the frequency of SCEs was varied by changing either the BUdR concentration at a fixed BUdR substitution (60%) or the BUdR substitution at a fixed BUdR concentration (12 μM). The effect of mitomycin C (15 or 30 ng ml^{-1}) in inducing SCEs in the various conditions was determined, and in no case was there evidence for interactions between BUdR and mitomycin C. For example, in FBT medium with a 3:2 ratio of BUdR:dT, 30 ng ml^{-1} mitomycin C caused an increase of 96.9 and 95.3 SCEs per cell above the baseline for BUdR at 12 μM (9.3 per cell) and 180 μM (23.3 per cell), respectively. These results agree with those of a previous study in which BUdR concentration and substitution effects were not tested separately¹³.

The results presented above show that (1) the major factor in determining the frequency of SCEs induced by BUdR is the concentration of BUdR in the medium, (2) the amount of BUdR in DNA has only a small role in determining the frequency of SCEs, (3) the induction of SCEs by high concentrations of BUdR can be suppressed by dC without changing the amount of BUdR in DNA, and (4) the induction of SCEs by high levels of BUdR substitution is not suppressed by dC. Overall, there was a reasonably good correlation between SCEs and mutations,

although conditions to separate these two effects of BUdR were found.

The specific mechanism by which BUdR induces SCEs remains to be elucidated. However, the results presented above suggest that the primary effect of BUdR in inducing SCEs may

Fig. 3 Effect of deoxycytidine on the induction of SCEs by BUdR. The analyses were carried out as described in Fig. 1 legend. The cells were exposed to BUdR in FBT medium with a 3:2 ratio of BUdR:dT. Half the cultures received 200 μM dC (○) at the same time that BUdR was added, the other half received no dC (●).

occur at a site outside DNA (although the ultimate target for SCEs is obviously DNA). One possibility raised by our results is that perturbation of dC metabolism has a key role in the induction of SCEs by high concentrations of BUdR, as previously suggested for BUdR mutagenesis^{2,3,14,15}. The induction of SCEs and mutations by high BUdR concentrations could involve a common site outside DNA, possibly the inhibition by BUdR triphosphate¹⁶ of the ribonucleotide reductase-catalysed reduction of CDP to dCDP. The fact that dC did not suppress the (small) increase in SCEs caused by increasing the level of BUdR substitution suggests that the independent effects of BUdR substitution and concentration on SCEs might involve different mechanisms. Of the two components of the effect of BUdR on SCEs, the minor component (BUdR substitution) may be directly related to the presence of BUdR in DNA, whereas the major component (BUdR concentration) seems to involve other sites.

Influence of local vascularity on hormone receptors in mammary gland

Brian P. Moore* & Isabel A. Forsyth†

National Institute for Research in Dairying, Shinfield, Reading RG2 9AT, UK

Procedures, such as teat removal (thelectomy) or teat duct ligation, which prevent removal of milk, lead to rapid involution of the lactating mammary gland; performed unilaterally they have been used previously to study the biochemistry of involution¹⁻³, enabling a comparison of normal and involuting glands in the same animal against the same systematic hormonal environment. Both the protein hormone prolactin and the steroid hormone oestrogen are of importance in the development and function of the mammary gland⁴. In the present experiments, female Sprague-Dawley rats were unilaterally thelectomised and the binding to the mammary gland of prolactin and oestrogen was examined through pregnancy, lactation and weaning. There was an effect of thelectomy during lactation only, when levels of both receptors increased in the intact lactating gland but failed to rise in the thelectomised, involuting gland. Capillary closure is known to occur in the mammary glands of rats after 36–48 h of milk accumulation⁵. The rate of delivery of hormones to the tissue will be drastically reduced and it is concluded that this, rather than systemic hormone levels, is of importance in controlling receptor levels.

Female Sprague-Dawley rats aged 34–45 days were unilaterally thelectomised under ether anaesthesia by ligation of milk ducts and excision of teats. Rats were allowed to recover for at least 21 days, and were then placed with a male for 4 days. The stage of pregnancy was confirmed at autopsy by inspection of pup development. The day of littering was day 1 of lactation. Litters were adjusted to 6 pups per dam and pups were weaned on day 21 of lactation. All animals were killed by stunning and immediate decapitation between 09.00 h and 11.00 h (lights on 08.00–20.00 h). Because of the small amounts of mammary tissue in virgin and some early pregnant females, mammary tissue from two or three animals was pooled for hormone binding measurements at these stages. Mammary glands were removed, placed on ice, blotted and weighed. The wet weight of mammary tissue reflected expected developmental changes, rising slightly between early and late pregnancy and increasing a further twofold in lactation in intact glands. Mammary weight differed between intact and thelectomised glands only during lactation. Thelectomised glands were about 60% of the weight of intact glands between 2 and 7 days post partum, falling to 40% in late lactation, equal to the weight in weaned rats, thereby demonstrating progressive involution.

To measure hormone receptors, mammary tissue was immediately cut into small pieces and homogenised in 3 volumes (w/v) of ice-cold buffer (0.01 M Tris-HCl, 0.0015 M EDTA, 0.012 M thioglycerol, pH 7.4, containing 10% glycerol, v/v), using 10-s bursts of a Silverson laboratory mixer-emulsifier at maximum speed with 30-s cooling periods until no solid material remained (three to six bursts). The total homogenate was centrifuged at 15,000g for 20 min (4 °C), the pellet and floating fat were discarded and the aqueous supernatant was centrifuged at 100,000g for 1 h. The supernatant (cytosol fraction) and the pellet (membrane fraction) were stored at –20 °C until assayed for oestradiol binding and prolactin binding respectively.

Table 1 Specific binding of ¹²⁵I-labelled ovine prolactin to intact and operated mammary glands of unilaterally thelectomised rats

Rats	¹²⁵ I-ovine prolactin bound (c.p.m. per 0.1 g wet weight mammary gland)		Significance
	Intact mammary gland	Thelectomised mammary gland	
Virgin (n = 4)	872 ± 193	643 ± 296	NS
Early pregnancy (1–11 days) (n = 6)	863 ± 538	1,585 ± 1,208	NS
Late pregnancy (12–22 days) (n = 9)	2,615 ± 2,054	1,768 ± 1,429	NS
Early lactation (2–7 days) (n = 6)	5,394 ± 1,446*	1,312 ± 1,109	P < 0.002
Late lactation (8–21 days) (n = 7)	6,531 ± 1,956	1,050 ± 778	P < 0.001
Weaned (5–12 days) (n = 6)	906 ± 808†	588 ± 338	NS

Prolactin binding was assayed in the membrane fraction (100,000g pellet) as previously described⁶. Ovine prolactin (NIH-P-S6) was iodinated to a specific activity of 22–48 µCi µg⁻¹ and 40,000 c.p.m. added to each assay tube. Values are means ± s.d.; n = no. of observations; NS, not significant, P > 0.05, Student's *t*-test.

* P < 0.001 versus intact mammary gland of virgin rats.

† P < 0.001 versus intact mammary gland of lactating rats.

The binding of prolactin (Table 1) and of oestradiol (Table 2) were measured in intact control mammary glands and in the contralateral thelectomised mammary glands of 9 virgin, 17 pregnant, 13 lactating and 6 weaned rats. Glands from virgin females showed low levels of prolactin and of oestradiol binding and there were no significant effects of thelectomy. Binding remained low during the early stages of pregnancy. After mid-pregnancy, prolactin binding tended to increase more in intact than in thelectomised glands but there were no significant differences between intact mammary glands of rats in early and late pregnancy or between intact and thelectomised mammary glands in late pregnancy. Oestradiol binding tended to be lower in late pregnant than in virgin females in both intact and thelectomised glands.

From the onset of lactation there were highly significant differences in prolactin binding between intact and thelectomised mammary glands. By 2–7 days post-partum, prolactin binding had increased in intact glands to two to three times the levels in late pregnancy, and five to six times the levels in the virgin gland, while in thelectomised glands, prolactin binding had returned to levels seen in virgin females. Prolactin binding in intact glands remained high throughout lactation and had returned to the levels in virgin females by 5 days after weaning, when they were not significantly different from the thelectomised glands.

Oestradiol binding increased in intact mammary glands in early lactation and continued to rise as lactation progressed, falling again to the levels seen in virgin females after weaning. In thelectomised glands there was no rise in oestradiol binding, which remained at the levels seen in late pregnancy.

The observations on binding of prolactin and oestradiol to the intact mammary glands confirm previous results in the rat showing marked elevation of both prolactin⁶⁻⁹ and oestradiol⁹⁻¹³ binding in lactation. The failure of prolactin and oestradiol binding to rise after removal of the young on the day of littering has been previously reported⁹, but in the present experiments it is striking that this occurred in the thelectomised glands of rats which were suckling pups on their intact glands and whose serum levels of prolactin would be markedly elevated for at least 15 days⁹. Oestrogen binding to rat mammary tissue is unaffected by ovariectomy¹¹, but increased by prolactin¹⁴. Prolactin binding is increased by prolactin itself and by oestrogen, acting at least in part by stimulating plasma prolactin levels (see ref. 6 for review).

Table 2 Specific binding of ^3H -oestradiol to intact and operated mammary glands of unilaterally thelectomised rats

Rats	^3H -oestradiol bound (fmol per mg cytosol protein*)		Significance
	Intact mammary gland	Thelectomised mammary gland	
Virgin ($n=4$)	10.8 ± 5.1	9.25 ± 4.75	NS
Early pregnancy (1–11 days) ($n=6$)	6.7 ± 5.4	10.2 ± 10.3	NS
Late pregnancy (12–22 days) ($n=9$)	4.9 ± 4.1	4.3 ± 5.7	NS
Early lactation (2–7 days) ($n=6$)	$8.7 \pm 4.1^\dagger$	4.7 ± 3.8	NS
Late lactation (8–21 days) ($n=7$)	20.9 ± 15.1	5.0 ± 3.7	$P < 0.02$
Weaned (5–12 days) ($n=6$)	8.6 ± 4.1	3.2 ± 3.1	$P < 0.03$

Oestradiol binding was assayed in the cytosol fraction (100,000 g supernatant). Cytosol plus buffer (500 μl) was incubated overnight (5°C) with saturating amounts (2 pmol) of [$6,7\text{-}^3\text{H}$]oestradiol-17 β (44 Ci mol $^{-1}$, Radiochemical Centre, Amersham) in the absence and presence of unlabelled oestradiol (2 nmol). Unbound steroid was removed by incubation at 0°C for 15 min with dextran-coated charcoal (1 ml 0.5% activated charcoal, Sigma, 0.05% dextran T80, Pharmacia). Charcoal was precipitated by centrifugation (1,500g for 10 min) and the supernatants decanted into 10 ml Instagel scintillation phosphor (Packard) and the radioactivity determined using a Packard TriCarb B2450 liquid scintillation counter, with automated external quench correction. The binding was specific for oestrogens being displaced by oestradiol and diethylstilboestrol, but not by testosterone, dexamethasone, cortisol or progesterone. Values are means \pm s.d.; n = no. of observations; NS, not significant, $P > 0.05$.

* Protein measured by a modified Lowry method¹⁸.

$^\dagger P = 0.03$ versus mammary gland in late pregnancy.

When teats are blocked, ligated or removed, milk accumulates in the mammary gland. Early changes depend on whether the litter remains with the mother. If the litter is removed, then even in intact glands milk accumulates and mammary blood flow falls within 8 h as a result of reduced cardiac output and a reduced proportion of cardiac output being taken by the mammary gland¹⁵. If, as in the present experiments, suckling continues but milk removal is prevented, then even more milk collects in the tissue but the blood flow does not fall¹⁵. However, by 36–48 h capillary closure occurs in the mammary gland whether suckling occurs or not⁵, and there is marked reduction in metabolic activity^{1–3}. The collapse of the capillary bed can be seen by blanching of the tissue and was further demonstrated by Silver⁵ by failure of the gland to give a milk ejection response to oxytocin administered intravenously, whereas a response could still be obtained if oxytocin was applied locally to the exposed surface of the gland. Capillaries remained empty beyond 120 h in suckled glands⁵. As involution progresses, the proportion of cardiac output going to the mammary gland falls, apparently regulated locally by depressed mammary activity^{15,16}.

Our results indicate the importance of blood supply and rate of delivery of hormones to the tissue in the control of receptor levels. This could be of considerable importance in the regulation of receptor levels in breast cancer tissue, since angiogenesis, blood vessel development, is stimulated by neoplastic cells¹⁷.

We thank NIAMDD, Bethesda for the ovine prolactin and the Cancer Research Campaign for a grant; also Mrs L. Schofield and Miss K. Woodsell for technical assistance.

Novel expression-linked copies of the genes for variant surface antigens in trypanosomes

J. H. J. Hoeijmakers, A. C. C. Frasch, A. Bernards, P. Borst & G. A. M. Cross*

Section for Medical Enzymology and Molecular Biology, Laboratory of Biochemistry, University of Amsterdam, Jan Swammerdam Institute, PO Box 60.000, 1005 GA Amsterdam, The Netherlands

*The Wellcome Research Laboratories, Department of Immunochimistry, Langley Court, Beckenham, Kent BR3 3BS, UK

Pathogenic African trypanosomes evade the immune system of their mammalian hosts by the sequential expression of alternative cell-surface glycoproteins (reviewed in refs 1, 2). Variant surface glycoproteins (VSGs) purified³ from cloned variants of *Trypanosoma brucei* have similar molecular weights (about 60,000), but differ in amino acid composition³, N-terminal amino acid sequence⁴ and C-terminal structure⁵. We have cloned DNA complementary to the messenger RNAs for four immunologically distinct VSGs⁶ and hybridised these complementary DNAs (cDNAs) with restriction digests of *T. brucei* nuclear DNA, fractionated by gel electrophoresis and transferred to nitrocellulose strips. Each cDNA recognises a unique set of fragments and this basic set is present unaltered in the nuclear DNAs from the four variants. In addition, each probe recognises an extra fragment only in nuclear DNA isolated from cells expressing the VSG corresponding to the cDNA probe. We infer that activation of a VSG gene involves the production of an expression-linked copy of that gene.

The cDNA clones used in our experiments were originally identified⁶ on the basis of their ability to hybridise only to poly(A)⁺ RNA from the homologous variant and this specificity is further documented in Fig. 1. Total poly(A)⁺ RNA from all four variants of *T. brucei*, strain 427, was size-fractionated by agarose gel electrophoresis (Fig. 1a), covalently linked to paper⁷ and then hybridised with one of the four cloned cDNAs. Figure 1b shows that cDNA of variant 117 only hybridises with homologous RNA; the same was found with the other three cDNAs (not shown). The mobility of the RNA species that hybridise is variant dependent (Fig. 1c), the calculated size varying from 2,250 nucleotides (variant 117) to 1,950 nucleotides (variant 221)⁶. This variation correlates with the apparent molecular weights of the corresponding pre-VSGs, deduced from their mobilities in SDS polyacrylamide gels. These decrease in the same order, 117 being 62,000, 221 being 52,000 (ref. 6).

The genes corresponding to these VSG-specific cDNAs were analysed by the Southern blotting technique⁸. Nuclear DNA from one *T. brucei* variant was digested with various restriction endonucleases, size-fractionated by agarose gel electrophoresis, blotted on to nitrocellulose strips and hybridised with each of the four cDNAs. Figure 2 shows results with three of these. Each

Fig. 1 Hybridisation of cloned cDNA with poly(A)⁺ RNA from the homologous variant and other variants. Glyoxal-treated poly(A)⁺ RNA (2 µg) from each of the four trypanosome variants was electrophoresed through a 1.75% agarose gel in Tris-borate buffer¹⁶. After transfer of the RNA to diazobenzoyloxymethyl paper⁷, the filters were hybridised with nick-translated recombinant plasmid DNA containing sequences complementary to VSG mRNA⁶. *a*, Photograph of the ethidium-stained gel after electrophoresis; lane 1, variant 117 RNA; lane 2, 118 RNA; lane 3, 121 RNA; lane 4, 221 RNA. The large rRNA contains an internal break and yields two bands. *b*, Autoradiogram of the RNA in *a* after transfer to diazobenzoyloxymethyl paper and hybridisation with a recombinant plasmid containing DNA complementary to VSG 117 mRNA (T-cV117-1). *c*, As *b*, but each RNA hybridised with the homologous cDNA probe; lane 1, T-cV117-1; lane 2, T-cV118-2; lane 3, T-cV121-3; lane 4, T-cV221-12. (Figure assembled from different replica gels.) The recombinant plasmids were made by inserting duplex DNA complementary to VSG mRNA into the *Pst*I site of plasmid pBR322 by the dG-dC tailing technique⁶. The sizes of the inserts are (in base pairs): T-cV117-1, 820; T-cV118-2, 1,500; T-cV121-3, 800; T-cV221-12, 1,200. See ref. 6 for isolation of poly(A)⁺ RNA, plasmid isolation, ³²P labelling of DNA by nick-translation, gel handling and other evidence that the cDNA inserts of these four plasmids have no sequence homology under standard hybridisation conditions.

cDNA hybridises to a different set of bands, confirming that each probe 'sees' different genes, as anticipated from Fig. 1. The 118 and 121 probes hybridise mainly to one or two bands in each digest, indicating that they primarily recognise one gene. At long exposures other faint bands become visible, suggesting that the probes cross-hybridise to other genes that show partial cross-homology with the 118 and 121 genes. The 117 cDNA probe hybridises to many different bands in all digests. We attribute this to extensive cross-hybridisation to a family of related VSG genes, because more stringent washing of the hybrids (in 0.1 × SSC at 60 °C) removes the label from all but a few of these bands (not shown). An even more complex pattern has been found with the 221 cDNA (not shown).

There are no differences between the *Hap*II and *Msp*I digests for any of the probes. Both enzymes recognise the sequence CCGG, but cleavage by *Hap*II is prevented by methylation of the C in the CpG doublet, whereas cleavage by *Msp*I is not⁹. Partial methylation of C in the CpG sequence, therefore, does not complicate the digests shown here.

To determine whether expression of a VSG gene results in sequence alterations in or around that gene, we compared the

hybridisation of each cDNA probe with homologous and heterologous nuclear DNA digests. Figure 3 shows results with the 118 cDNA probe. In each digest this probe sees one DNA fragment more in the homologous 118 nuclear DNA than in the heterologous 117 DNA. We attribute the fragments common to the 117 and 118 DNA digests to a basic copy of the 118 VSG gene, present in both variants. The results of double digestion experiments with two restriction enzymes fit a *Pst*I × *Eco*RI × *Bam*HI × *Hind*III map of this basic copy which accounts for all

Fig. 2 Autoradiogram of variant-specific cDNA probes hybridised to restriction enzyme digests of nuclear DNA from *T. brucei* variant 118. Nuclear DNA was isolated by a modification of the kinetoplast DNA isolation procedure¹⁷, digested in standard conditions¹⁷ with the enzyme indicated and electrophoresed through a 0.6% agarose gel¹⁷. The gel was blotted on to nitrocellulose filter strips as described elsewhere⁸ and hybridised with nick-translated DNA from the recombinant plasmids indicated. See Fig. 1 legend for further details. Probes: *a*, T-cV117-1; *b*, T-cV118-2; *c*, T-cV121-3.

fragments seen in blots without invoking intervening sequences or the presence of more than one basic 118 VSG gene. In each digest shown in Fig. 3 the 118 cDNA probe hybridises to one extra band in the homologous 118 nuclear DNA, not present in the 117 nuclear DNA. An extra band was also found in the *Mbo*II, *Hap*II and *Msp*I digests (not shown). We attribute these extra bands to an additional expression-linked copy of the 118 VSG gene only present in 118 nuclear DNA.

Analogous results were obtained with the 117 and 121 cDNA probes. Figure 4 shows that the fragments hybridising with the 117 cDNA are identical except for an extra band in the *Msp*I digest of the homologous 117 nuclear DNA. Extra bands only in homologous DNA were also observed in the *Hap*II, *Eco*RI and *Pst*I digests (not shown), but not in *Bsp*I (Fig. 4) and *Mbo*II digests (not shown). The fact that an extra band does not appear in all digests of homologous DNA is not surprising. If the sequences around a gene change, this will only result in altered fragments in blots if the enzyme used cuts far enough from the gene segment recognised by the probe to include the altered sequence. The results with the 121 cDNA are more complex. In this case extra bands are observed in both the 121 and the 221 nuclear DNAs, but the extra bands are not identical in size. It is of interest that variant 221 has arisen during *in vitro* culture from variant 52, which is immunologically identical to variant 121 (ref. 10). The extra band in the 221 digest could, therefore, represent an inactivated form of the expression-linked copy of the 121 gene, but this is only one of several possibilities.

Analysis of several blots like those shown in Fig. 3 has yielded no reproducible differences in the relative intensities of the

[illegible]

Fig. 3 Hybridisation of DNA complementary to VSG 118 mRNA to nuclear DNA digests of variants 117 and 118. The restriction digests were electrophoresed through a 0.7% agarose gel. Further conditions as in Fig. 2. The p marks persistent partial *Hind*III digestion products, absent in other experiments. Lane 1, nDNA 117; lane 2, nDNA 118; P, *Pst*I; B, *Bam*HI; H, *Hind*III; E, *Eco*RI.

To account for the results of the blotting experiments, the formation of the expression-linked copy must be associated by a reshuffling of DNA sequences which alters the neighbouring sequences. This reshuffling could either move the gene into a new (expression) site¹²⁻¹⁴, as in the cassette mechanism for mating-type switching in yeast¹⁴, or an insertion sequence could be put next to the extra copy¹⁵. Whatever the mechanism, the sequences flanking the expression-linked copy of the VSG 118 gene are unusual in that at one side no *Pst*I, *Hind*III, *Bam*HI or *Eco*RI site is present within 8 kilobase pairs of the gene. It is interesting that large extra bands have also been observed when the 117 cDNA is hybridised with 117 nuclear DNA cleaved with *Msp*I (Fig. 4), *Pst*I or *Eco*RI. The flanking sequence, may, therefore, be similar whatever alternative gene is being expressed. The simplest interpretation of our results is that the expression-linked copy is the one transcribed and that the novel flanking sequences are responsible for this; however, this remains to be confirmed.

The recombination event that we expect to be responsible for the positioning of the extra copy in the postulated expression site could easily be accompanied by further recombination events that increase sequence diversity in the VSG genes. There is no

Fig. 4 Autoradiogram showing hybridisation of VSG-specific cDNA probes with homologous and heterologous nuclear DNAs. Nuclear DNA from the four variants indicated was electrophoresed through a 1.2% agarose gel; see Fig. 2 legend for further details. nDNA: a, 117; b, 118; c, 121; d, 221.

evidence for this either in previous work on VSGs (refs 2-5 and G.A.M.C., unpublished) and their genes⁶, or in our present experiments, as the expression-linked copy is not recognised by the heterologous probes tested. It seems likely, therefore, that antigenic diversity in trypanosomes is genomic and finite and not created by a clever reassortment of a limited number of DNA sequences to yield an unlimited number of VSG genes. It is possible, however, that the novel flanking sequence in the expression site provides not only a promotor but also the 5'-leader sequence and signal peptide (if present) for each VSG. This can be tested when genomic clones are available; work is in progress to obtain them.

Williams and coworkers¹⁸ have also observed rearrangement of DNA associated with expression of another line of *T. brucei*. In their case, however, there is no clear conservation of bands associated with a basic copy and, moreover, there are also alterations in another clone apparently not associated with expression. We cannot account for this crucial difference from our results.

We thank Miss J. Van den Burg and Mr M. J. Hillebrand for assistance and Professor C. Weissmann for providing plasmid DNAs. This work was supported in part by a grant to P.B. from BION (ZWO) and a Research Training Grant to A.C.C.F. from WHO.

Spiders

E.O. Wilson: Let me remind you that people everywhere, a large percent of the population, at a very early age have already developed a deep horror at the sight of snakes or spiders with nothing more than gentle nudging from their parents, if that. Yet, in spite of the fact that parents constantly reinforce their children against going near electric sockets, automobiles, knives and the like, phobias against such objects rarely develop.

Marvin Harris: Let's go back again to the possibility that these phobias are genetically programmed — which I'm willing to grant. The overwhelming bulk of the socially conditioned response repertoires of different human societies consists, by your own admission, of culturally determined rather than genetically determined traits. Then it seems to me that when one offers a cogent culturological explanation of these phobias, one has to be considered that this explanation is not offered in isolation.

... from a debate between E.O. Wilson and Marvin Harris on sociobiology. In *The Sciences*. From family constellations to galaxies, *The Sciences* takes the critical look. Handsome, original, lively, *The Sciences* represents the best science commentary you'll find anywhere on human behavior, culture, the physical sciences — by Ashley Montagu, Stephen Jay Gould, B.F. Skinner, Napoleon Chagnon, Peter Medawar. ... Subscribe today. It's only \$12.50 a year.

Endurance of Life

The Implications of Genetics for Human Life
SIR MACFARLANE BURNET

This important and controversial book is concerned with the description and interpretation of human ageing in terms of genetics. The author also applies the same biological approach to all aspects of human behaviour and criticises the failure by most modern writers to realise the importance of genetic constitution. This book will be read by professionals in the field and general readers alike.

Invertebrate Animals

Collection and Preservation
ROGER J. LINCOLN and J. GORDON SHEALS

The first chapter of this book reviews the morphology, classification and biology of all the invertebrate groups, except for insects, and provides notes on the techniques for collection and preservation recommended by appropriate specialists. Subsequent chapters deal with collecting equipment, field techniques, fixative/preservative formulations, and the general treatment of collections. The complete text thus forms a comprehensive well-illustrated manual which will be useful to undergraduates, research workers and amateur naturalists.

Handbook of Phycological Methods

Culture Methods and Growth Measurements
Edited by JANET R. STEIN

The hard cover edition of this work has become a standard and highly praised compendium of techniques for culturing and measuring growth of those organisms collectively known as algae. This paperback edition will make an important reference source available to an even wider audience of students and research workers in phycology, plant physiology, marine biology, biochemistry and morphology.

The Dynamics of the Upper Ocean

Second Edition
OWEN M. PHILLIPS

'In fine, this second edition is a significant improvement on the original and should be welcomed by the geophysical-fluid-dynamics community... it is written with the same grace and verve that I found so attractive in the original and continues to provide the best available account of the dynamics of the upper ocean.'

The Human Biology of Circumpolar Populations

Edited by F. A. MILAN

This comprehensive study of circumpolar populations, including the Eskimos, Lapps and Ainu and certain groups in the Soviet Arctic, considers the demography, genetics, craniofacial development, growth, ophthalmology, nutrition, physiology and behaviour of the populations in question and elucidates the biological and behavioural processes leading to their successful adaptation to the harsh environment. This text will be of particular interest to students of human biology, medicine and anthropology, and to clinicians and public health practitioners. **£35.00 net**

International Biological Programme 21

An Introduction to Crop Physiology

Second Edition
F. L. MILTHORPE and J. MOORBY

This book discusses how the various physiological processes in plants are integrated to produce the appropriate responses to the variable environment in the field. The authors consider all relevant aspects of crop physiology, and the emphasis is on understanding and predicting productivity. The new edition takes into account recent developments in research and, like the highly praised first edition, it will be an invaluable textbook for students and research workers in plant physiology, horticulture, soil science, agronomy and ecology.

Soil Physics

T. J. MARSHALL and J. W. HOLMES

The central connecting theme of this account is the state of water in porous material, soil or deeper sediments. The authors show how water influences the physical properties of soils, how plants absorb water from soils under a variety of circumstances, how water drains through soils and produces saline soils and how the soil water supply influences the rate of evaporation from the land. The emphasis on field applications will make this account invaluable to professionals and students of soil science, agriculture, hydrology, botany, civil engineering, geography and geology.

US COLLEGE TEXTBOOK SUPPLEMENT

Bringing physics to life

Daniel Zwanziger

Physics (Formerly Life Science Physics). By Joseph W. Kane and Morton M. Sternheim. Pp.664. (Wiley: New York and Chichester, UK, 1978.) £11. *General with Bioscience Essays*. By Jerry B. Marion. Pp.539 plus index. (Wiley: New York and Chichester, UK, 1979.) \$18.95. *Physics for Applied Biologists*. By N.C. Hilyard and H.C. Biggin. Pp.223. (University Park Press: Baltimore, 1977.) \$13.75. *Intermediate Physics for Medicine and Biology*. By Russell K. Hobbie. Pp.557. (Wiley: New York and Chichester, UK, 1978.) \$23.95.

It would be hard to overestimate the degree of penetration of the concepts of physics into biology. On the one hand, the conceptual barrier between the living and the non-living world has continually eroded as our detailed knowledge of biological processes has increased. On the other hand, the introduction of new instruments and techniques resulting from advances in physics has in many cases opened up whole new areas of biology. Today's laboratory investigators use sophisticated instruments to study the function of an organ, cell or macromolecule which is ultimately understood by means of a simple physical concept such as diffusion, electrical conduction or tunnelling through a potential barrier. The two principal themes are entropy and energy which distinguish spontaneously occurring processes, namely those accompanied by an increase of entropy from active or pumped processes where entropy decreases at a cost of energy. The detailed knowledge of living things achieved by present day biologists is a triumph of the mechanistic world view in which, to be sure, quantum mechanics plays an important role. It is well recorded in Jacques Monod's broadly painted overview of biology *Le Hasard et la Nécessité* (Editions du Seuil, Paris, 1964).

It is fortunate that a number of texts have appeared to meet the need of the biologist to learn physics. Outstanding among these is *Physics with Illustrative Examples from Medicine and Biology* (Vol. 1: Mechanics by G.B. Benedek and

F.M.H. Villars; Vol. 2: Statistical Physics by F.M.H. Villars and G.B. Benedek; Vol. 3: Electricity and Magnetism by G.B. Benedek and F.M.H. Villars, Addison-Wesley: London and Reading, Massachusetts, 1973, 1974, 1979). These volumes are a milestone of pedagogy. They successfully integrate the history of the subject and the analysis of key experiments into its logical exposition. (This history reveals, incidentally, the corresponding debt of physicists to physiologists such as Volta, Mayer and Helmholtz, who in fact have made many of the important discoveries of physics.) These volumes provide a wealth of anatomical and physiological applications worked out in beautiful and patient detail. In the opinion of this reviewer they provide the best introduction available to statistical physics as pure physics, entirely apart from biological applications. Any text on the subject must be measured against the standard which they set. It seems, however, that the blinding light of truth cannot be revealed all at once to the uninitiate, and

that the content of these volumes is too rich for a first introduction to physics for those whose main interest is in the life sciences, and who generally take only two semesters of college physics. However, they make a wonderful text for an intensive three-semester introductory course in physics if the students are reasonably well motivated.

A number of texts have been published in recent years for a two-semester introductory course in physics with applications in the life sciences. Of those which this reviewer has examined, perhaps a dozen in all, the best by far, in his opinion, is *Physics (Formerly Life Science Physics)* by Kane and Sternheim. Most of these texts, written by physicists for the pre-medical student market, are basically standard physics texts with occasional applications of biology. The conspicuous virtue of the text by Kane and Sternheim, which distinguishes it from its competitors, is the breadth of coverage of the many subfields of physics and the remarkable completeness of the quantitative applications to the life

Sir John Kendrew and his model of myoglobin — the first protein to yield its structure to the physics of X-ray diffraction.

sciences. The latter, taken together, could constitute the core of an introductory course in biomechanics and biophysics. The authors achieve this without sacrificing the derivations which are the meat of any course in physics, by clear and concise writing which allows them to present more on each page than the other texts. The wealth of material may be used selectively to advantage emphasising either the basic physics or the life science applications. Derivations which use calculus are segregated to the end of each chapter. There are abundant homework problems of graded levels of difficulty.

General Physics with Bioscience Essays by Jerry B. Marion is a text for a one-year non-calculus terminal course in physics. Though only slightly shorter than *Physics (Formerly Life Science Physics)* by Kane and Sternheim, it contains fewer derivations and fewer and less detailed life science applications, with no corresponding gain in clarity.

Physics for Applied Biologists by N.C. Hilyard and H.C. Biggin is a useful compendium of formulae and diagrams of instruments. However, to this reviewer's mind it is not really a physics text at all because derivations, as examples of physical reasoning, are almost entirely lacking. If physics-for-biologists texts become distinguished from pure physics texts by the absence of reasoning, they will

contribute to the division of the house of science instead of its unity. The phenomenon is before us in the statistics-for-social-scientists texts, generally written by social scientists instead of mathematicians, in which the subject is deprived of its logical structure and reduced to a verbose hodge-podge and unrelated formulae, because it is assumed that the student is incapable of understanding a logical derivation. The vicious circle is fatally closed when the student does indeed conclude that he is incapable of understanding statistics.

Intermediate Physics for Medicine and Biology by Russell K. Hobbie brings together material not readily available elsewhere. It is the only text on the subject, which this reviewer has seen, in which a knowledge of calculus and a previous acquaintance with physics are assumed. The author was motivated by the sophisticated level of physics applications in medical school courses and the poor preparation in physics prevalent among medical students. He has an ambitious aim, namely a logically complete though concise presentation of physics, without reliance on "it can be shown", though the main body of the text is devoted to applications in the life sciences. The result is successful. For example, the brief introduction to statistical physics is applied effectively in subsequent chapters to the phenomenon of

osmotic pressure and transport through membranes. Similarly, sufficient electricity and circuit theory are presented for a cogent exposition of the Hodgkin-Huxley model of nerve conduction and the electrocardiogram. The quantum effect in dark-adapted vision, discovered by Hecht, Schlaier and Pirenne, is clearly explained. It would be helpful if, in a new edition, more anatomically correct drawings accompanied the physicist's schematic or block diagrams. This text is both competitive with and complementary to the volumes by Benedek and Villars which I praised above. There is considerable overlap of subject matter, but Hobbie assumes greater background on the part of the student and thus can be more concise. His book would make an excellent text for an upper division undergraduate course. Such a course could profitably be introduced in many universities. For physics students it would be a valuable introduction to applications in the life sciences which may offer them interesting career opportunities. It would be invaluable for graduate students preparing for research in the life sciences, where the concepts of physics have assumed overwhelming importance. □

Daniel Zwanziger is Professor of Physics at New York University.

Physics starts here; or here?

David J. Miller

Concise Dictionary of Physics. By J. Thewlis. Pp.366. (Pergamon: Oxford and New York, 1979.) £20.00. *Introductory Physics.* By M.L. Warren. Pp.683. (Freeman: San Francisco and Reading, UK, 1979.) £20.50. *Physics.* By Jay Orear. Pp.752. (Collier-Macmillan: London, 1979.) £13.50.

SHOULD physics be taught as a body of facts or as a system of ideas? These three books at introductory college level reflect the most divergent of views.

The *Concise Dictionary of Physics* claims in its preface to be intended not only for students but also for teachers, engineers, journalists and for the interested layman. It is surely a useful compilation; by no means comprehensive but amazingly good for 370 pages, and admirably concise. In sampling an arbitrary list of topics which I had decided in advance it ought to contain only one was missing — Clebsch-Gordan coefficient. There are few inaccuracies, though baryons are no longer those "fermions with mass greater than or equal

to that of the nucleon". The chief criticism to be made is not of the dictionary's accuracy but of its relation to the rest of the world of physics. Concepts here are "formulated, sprawling on a pin", lifeless and unconnected with the world in which they live. When so much trouble has been taken to write the definitions it seems perverse not to offer references to textbooks, or bibliography. I would like to know what a "quaternion" is, for instance. Where do I go next after reading that it is "an operator, in a system of vector analysis invented by Hamilton, which changes one vector into another by rotation accompanied by a change of magnitude"?

Jay Orear's *Physics*, an introductory textbook for science and engineering students, goes to the other extreme. He begins by saying that the goal of physics is "to seek out and understand the basic laws of nature upon which all physical phenomena depend." The book reflects this statement, with a methodical progression from mechanics to special relativity, followed by heat and thermodynamics, then electricity and magnetism, waves and optics, quantum physics, atoms, molecules, solids, nuclei, astrophysics and particles. It is assumed that students will learn calculus in parallel with this course, so he is able to present the "basic laws of nature" in their

mathematical form. This is not a book for biologists or medical students, but physics students will want a more complete account of each of the subjects introduced here. In 752 spaciouly laid out pages there is no room for detailed experimental justification of many of the assertions made and there are surprisingly few illustrations. Its use will probably be in those universities where an introductory physical-sciences class is given high powered courses in mathematics, physics and chemistry before separating into specialised groups. Compared with a rival such as the three-volume *Fundamental University Physics* by Alonso and Finn (Addison-Wesley: Reading, Massachusetts and London, 1967), this book has the advantages of being up to date and short enough for the logical structure of the whole subject to be clear. There are twenty or thirty problems at the end of each of the thirty chapters, with answers to the odd-numbered problems at the back. A bibliography of more specialised texts would have been useful.

Introductory Physics by Mashuri L. Warren is aimed at biologists and medical students. My only objection to it is that its organisation is sometimes more like that of Thewlis' dictionary than can really be justified in a textbook. Where Orear never loses sight of physics as a unified system of ideas, Warren treats it as a body of often

unconnected facts. A strange example is the treatment of the equivalence of mass and energy, attributed to Einstein and discussed in some detail, but in no way related to the subsequent chapter on the special theory of relativity. But, having grumbled a little, let me say what a useful book it is. It crams an enormous amount into 683 double-columned pages, with line drawings or photographs of equipment on every page. Because the student is assumed weak in mathematics, most results quoted

are backed up by generous experimental — even anecdotal — detail, as well as some basic mathematical exposition. Physics for its own sake gets little space — particle physics hardly figures at all — but there is a chapter on electric shocks and electrical safety which taught me a great deal that I should have known before; and the chapters on optics and hydrodynamics are sensible and detailed. There are twenty or thirty simple problems at the end of each chapter, with answers to the odd numbers

at the back. The bibliography for each chapter is eclectic — not many specialised textbooks but a range of historical material, memoirs of scientists and *Scientific American* articles. There are appendices on basic mathematics, physical constants and units, ‘well known functions’ and problem-solving with calculators. □

David J. Miller is a Lecturer in the Department of Physics and Astronomy, University College London, UK.

Remote sensing of the environment

R.N. Colwell

Introduction to Remote Sensing of the Environment. Edited by Benjamin F. Richason Jr. Pp.496. (Kendal/Hunt: Dubuque, Iowa, 1978.) \$27.00. *Laboratory Manual for Introduction to Remote Sensing of the Environment.* Edited by Benjamin F. Richason Jr. Pp.237. (Kendal/Hunt: Dubuque, Iowa, 1978.) \$8.95.

THESE two books are companion volumes prepared by 24 contributors under sponsorship of the National Council for Geographic Education and published in the Council's Pacesetter Series.

The first chapter of the textbook provides a stage-setting overview. The second chapter describes the nature of electromagnetic energy and of basic matter/energy relationships. The next eight chapters describe various remote sensing devices and aerospace image acquisition systems; included are illustrations of the interpretation of black-and-white, colour, and colour infrared photographs, and of imagery acquired by thermal infrared scanners, multispectral scanners and microwave sensors. The next nine chapters deal with specific remote sensing applications including the analysis of landforms, rural cultural landscapes, agriculture, forestry, urban and industrial areas and weather phenomena; cartographic and regional planning applications are also included. The concluding chapter constitutes both a summary and a look to the future. The book's four appendices list sources from which remote sensing imagery and data tapes can be obtained, provide reference materials for beginning students, and present colour reproductions of various types of imagery. They are followed by biographical information about the contributing authors and a brief subject index. A much needed glossary is not included. The laboratory manual closely parallels the textbook, with appropriate emphasis on applications.

The scope of these two volumes is

excellent and the concept of multiple authorship is commendable. The quality with which the image examples are reproduced ranges from good to excellent and most of the writing is highly articulate. Closer study of the textbook suggests, however, that its chapters comprise more a compendium of separate treatises than a well integrated introduction to remote sensing. One manifestation of this is a lack of standardisation of terminology. For example, is ‘remote sensing’ (the most fundamental of terms) limited to the mere ‘imaging of features’, as defined in the Preface? Does it include the obtaining of digital records, as implied later in the text? In addition to data acquisition, is data analysis encompassed by this term? If so, does the analysis encompass work done not only by humans but also by machines? With respect to balance: (1) symptomatically, the chapter on agriculture planning is given roughly four times this emphasis in both respects; (2) of the 24 contributors, no less than 20 appear to be geographers; (3) more than half of the 24 colour plates pertain to features in the Great Lakes area; and (4) while the captions for a few of these colour plates are quite complete and are well cross-referenced to the two books, the captions for others indicate only the image type and/or geographic location.

Superficially, the laboratory manual is

very impressive, well illustrated and well matched to the supporting textbook. On a closer look, several of the exercises appear decidedly superficial. Also, the limited use of aerial photo stereograms gives the erroneous impression that three-dimensional perception and interpretation are of little importance.

There are notable strengths to offset these deficiencies. For example, Chapter 2 provides a masterful disclosure of some very important but highly complex material at a level that can be readily comprehended by most beginning students. Similarly, Chapter 16, dealing with regional planning, is clearly expressed, reasonably comprehensive, well balanced and well illustrated.

In summary, these two books represent a commendable effort to satisfy a long-standing need, that of providing the beginning student with a reasonably comprehensive remote sensing textbook and laboratory manual that might be digested in a single four- or five-unit course at the college or university level. A more carefully edited and better balanced second edition would far better satisfy this need. □

R.N. Colwell teaches courses in photo interpretation and remote sensing at the University of California, Davis, California.

Practical organic chemistry

J.E. Girard

Practical Organic Chemistry: A Basic Course. By V.V. Nekrasov. Pp.410. (MIR Publishers: Moscow, 1978.) \$7.80.

THIS fifth edition of a popular Russian text has been translated into English by Alexandar Rosinkin. What is not evident from the title of this book is that it is a laboratory text for students at vocational or technical school or for non-chemistry university students. As the author states in the introduction, this text is intended to be ‘only a practical manual, and it cannot rival the textbook of organic chemistry.

The theory is given in a limited scope’.

For the most part, the chapters are arranged according to functional groups. Within chapters are experiments dealing with qualitative organic analysis and simple synthesis. The latter chapters deal with polymer reactions, precipitation and denaturing proteins, hydrolysis of fats, preparation of mustard oils and reactions of carbohydrates.

Although this is a very thorough treatment, it is somewhat out of date. The translator has unfortunately chosen to use words or phrases that are not commonly used. This may cause beginning students undue confusion. □

J.E. Girard is an Associate Professor in the Department of Chemistry, College of Arts and Science, the American University, Washington DC.

Physical chemistry texts

David S. Kliger

A Textbook of Physical Chemistry. Second edition. By Arthur W. Adamson. Pp.953. (Academic: New York, 1979.) \$22.95. *Physical Chemistry.* Fifth edition. By Robert A. Alberty and Farrington Daniels. Pp.682. (Wiley: New York, 1979.) \$19.50. *Physical Chemistry: A Step-by-Step Approach.* By Marwin K. Kemp. Pp.1034. (Marcel Dekker: New York, 1979.) \$23.75.

In *A Textbook of Physical Chemistry* Adamson has put some new twists into the traditional format of physical chemistry texts. The ordering of topics, for instance, is significantly altered; a chapter on additive physical properties of matter appears near the beginning of the book. This chapter covers absorption of light, molar refraction, molar polarisation, and dipole moments. These topics would normally be found much later, after discussions of molecular structure. Another novelty is the placement of statistical mechanics in this text. Rather than devote a separate chapter to this topic Adamson includes discussions of statistical mechanics in chapters on thermodynamics. This makes the link between statistical mechanics and thermodynamics more apparent than in many texts.

Other non-standard features of this text include 'Commentary and Notes' and 'Special Topics' sections at the end of each chapter. These contain expansions of topics covered in the chapter, discussions of historical points of interest, and brief discussions of related topics. Unfortunately, some of these sections discuss material much more advanced than material covered in the related chapter. Also, many of the 'Special Topics' are topics normally discussed in physical chemistry texts. Here they are merely added at the end of chapters rather than integrated into the main text.

Overall, this book is a rigorous, rather sophisticated text that would make a fine reference source. It has a fine index and many good figures which help clarify the text. As a book to introduce students to the subject of physical chemistry, however, it seems too sophisticated. Many discussions are too advanced and the ordering of topics sometimes makes the material difficult to understand. There are many problems for students to solve, separated into sections of straightforward exercises, demanding problems, and special topics problems. These are fine learning tools for students. For all but the most sophisticated student, however, the main text will probably be difficult to follow.

Physical Chemistry, by R.A. Alberty and F. Daniels, is a rather traditional

textbook for a year-long physical chemistry course. It presents little history behind the subject areas or motivation for studying them. Instead, the emphasis seems to be on presenting formulae to be used in a physical chemistry course. This may be reasonable for use in a course based on a lecture format where the instructor provides background and motivation. This approach leads, however, to a rather dry text. Consistent with this format of a text to supplement lectures, the book presents many problems and answers to about half of them. This is probably the strongest feature of the book from the instructor viewpoint.

Treatments of various topics in the book vary greatly. Many topics are presented too tersely, making it seem that learning facts and formulae is more important than understanding underlying principles. This seems particularly true of the coverage of quantum theory and, to a lesser extent, of thermodynamics. Later sections covering Statistical Mechanics and Kinetics, however, are quite well done.

Some topics covered in this book, such as equilibrium for biochemical reactions, macromolecules, and surface thermodynamics, are not found in most textbooks of physical chemistry. They add a very nice supplement to the traditional topics found in most texts. On the other hand, these chapters again tend to emphasise facts rather than present a general overview of these special topics.

In all, this book would be useful in courses where lectures provide the primary source of fundamental material. It does not, however, stand on its own as a primary learning tool for physical chemistry.

Physical Chemistry: A Step-by-Step Approach, by M.K. Kemp, differs from

other physical chemistry texts in that it is designed for use in a self paced (sometimes called 'Keller Plan' or personalised system of instruction) course. In such a course there are often no lectures and the book becomes the primary source of information for students. Thus, the book must be very clear. This book is just that.

Each topic in the book is introduced with a statement of the importance of understanding the topic as well as a list of learning objectives the student must keep in mind. After discussion of each topic there are problems, with detailed solutions given in an appendix, and a self test. A detailed table of contents and a list of symbols and definitions also precede each topic to aid the student.

This book has very few weak points. There are not as many problems as one might wish and the introduction to quantum theory is weak. However, later sections on atomic structure and spectroscopy are excellent. Most topics are introduced at a very elementary level and progress through to a rather high level of sophistication. Treatments of real gases, colloid and surface chemistry, and polymers are particularly thorough.

In all, this is an outstanding text for physical chemistry courses using a self paced format or a standard lecture format. *Physical Chemistry*, by P.W. Atkins (Freeman: San Francisco, 1978), is the only other physical chemistry text this reviewer has seen which matches this book in clarity of presentation. □

Physical chemistry for the life sciences

R.M. Harris

Physical Chemistry with Applications to the Life Sciences. By David Eisenberg and Donald Crothers. Pp.868. (Benjamin Cummings: Menlo Park, California, 1979.) \$21.95.

THIS book surpasses all other life science-orientated physical chemistry texts I have examined in both the extent and depth of its coverage of traditional physical chemistry topics. Thermodynamics, solutions, electrochemistry, statistical mechanics and X-ray structure analysis are all presented at about the same conceptual and mathematical level as found in standard 'for chemists' texts, such as the most recent edition of *Physical Chemistry* by Moore (Prentice-Hall: Englewood

Cliffs, New Jersey, 1972). This is not to say it could replace a text like Moore's in a traditional two-semester 'for chemists' course. Its treatment of atomic structure and chemical bonding is neither extensive nor rigorous enough, and it has little to say about gas properties, kinetic molecular theory or reactions in the gas phase.

This text also has much to offer in the way of biological applications. Along with the usual topics (enzyme kinetics, transport properties, membrane equilibria, bioenergetics) it provides a more extensive treatment of macromolecular biophysics, including DNA characterisation, than any of the competing texts I know of, and it contains a lengthy qualitative section on the application of symmetry to the description of biological systems. Another attractive feature is that many of the mathematical results derived in the text are accompanied by a verbal description of their physical significance, and in most instances the explanations successfully illuminate the equations.

I was disappointed to find that several important biochemical topics normally included in a text of this kind were omitted by Eisenberg and Crothers. Aside from a paragraph on transition-state analogues, there is no discussion of enzyme inhibition, and there is nothing in the way of photochemistry or photobiology apart from a passing reference to photosynthesis. I also feel that the text needs more illustrations, and many that are present are too small or too sketchy. In

reading the sections on membrane phenomena, for example, I missed not seeing a picture of the modern model of a biological membrane, and the illustration accompanying the discussion of the hydrophobic effect did not help me at all in envisioning 'icebergs'. My most serious concern is that some of the major topics are developed in an unnecessarily formal manner. The reader has to labour through an entire chapter on principles of spectroscopy, and several sections of the

ensuing chapter, before encountering illustrative chemical examples.

Overall, the book's good points outweigh its shortcomings. You will want to give it serious consideration if you are seeking a text that offers life science students a solid foundation in physical chemistry. □

Biology from a human angle

M. Edidin

Inquiry into Life. Second edition. By Sylvia S. Mader. Pp.771 plus appendix, glossary, index. (Wm. Brown: Dubuque, Iowa, 1979.) \$15.95. *Biology. Human Perspectives*. By Charles Kingsley Levy. Pp.562. (Goodyear: Santa Monica, California, 1979.) \$17.95. *Man, Nature and Society. An Introduction to Biology*. Second edition. By E. Peter Volpe. Pp.662. (Wm. Brown: Dubuque, Iowa, 1979.) \$15.95. *Biology. A Human Approach*. Second edition. By I.W. and V.G. Sherman. Pp.636. (Oxford University Press: 1979.) \$16.95.

ALL four of these books aim to introduce biology to students beginning a college education. It must be assumed that such students have no background at all and instruction must begin with the most basic and general aspects of biology. The field is notable, even to one who works in it, as short on theories and general organism principles and long on variety. The broad problems of life — maintenance, regulation and reproduction — are approached in a bewildering diversity of forms and treated in many different ways by living organisms. How does an instructor construct an introductory course from such diverse material? The books under discussion do so by concentrating on the biology of a single species, humans, discussing important generalities in terms of human examples and then continuing with discussion of specific problems or processes peculiar to the species and its relatives. Around 98% of all organisms are excluded by this approach.

The reasons for concentrating on the biology of a single species are variously stated by the authors. Mader's book, *Inquiry into Life*, "emphasizes the application of this knowledge to modern concerns . . . biology is truly relevant." *Biology. Human Perspectives* by Levy aims to avoid fragmentation and to con-

centrate on the biology of the most intensively studied organism. He, too, feels that this biology will have the greatest "appeal, relevance and interest . . ." for students, busy enquiring humans that they are. Volpe in *Man, Nature and Society. An Introduction to Biology*, wishes to educate liberally, to present biology so that intelligent use can be made of it by humans who, though not extensively trained in science, can recognise the importance of biology in many social and ethical problems in society and can approach such problems thoughtfully and rationally. The Shermans in *Biology. A Human Approach* similarly hope to present information that will enable students "to understand themselves and the world in which they live." They, too, consider personal relevance and "areas of immediate human concern" important to their presentation. All the books, then, wish to show us biology epitomised in ourselves and as affecting us in the world today.

The four books, though attempting more or less the same feat, do not approach the subject with the same intellectual views, principles of organisation or physical orientation. Also, they do not seem intended for the same students. The intellectual level of the texts varies greatly, as does the emphasis on the material presented.

Before commenting specifically, I ought to note my own prejudices. First, I am not sure that the human organism is so interesting or so dominant that it is worth an entire general biology book. Many humans think otherwise; three of the texts considered here are in second editions. Second, to my mind, the only truly integrating approach to general biology is an evolutionary and genetic approach. Without this, texts fragment into sections not easily connected to one another. The first and second prejudices reinforce each other. Third, I have been teaching a general biology course, using several different texts, over the past eight years. My reactions to new texts are dulled, rather than heightened by the experience.

Of the four books, by far the most interesting, easy to read and best organised was Volpe's. Rather than begin with a discussion of 'life' and its origins, or with a long section on chemistry, Volpe begins

with a discussion of human reproduction, nicely balanced between endocrinology and anatomy. This is followed by an outstanding chapter on the control of fertility in humans which in turn is followed by a clear descriptive discussion of vertebrate development and birth. A clever transition is then made to consideration of the biochemistry needed for modern biology by considering the problem of trans-placental transfer of nutrients. We then return to cell differentiation and development. The section is concluded with seven clearly written chapters on physiology and endocrinology of adults. Two sections follow on genetics, evolution and population genetics. These constitute nearly half the material in the book and take the student from the chemical basis of inheritance via biochemical genetics and simple population genetic studies of selection and evolution, to questions of polygenic inheritance, speciation and adaptive radiation. The concluding section covers other aspects of populations and biological communities. Appendices on simple chemistry and on probability follow the body of the text. Throughout the writing is clear; transitions between subjects are deftly made, and the material is accurately presented. The standard of illustration is high; both colour photographs and coloured full page drawings are used in addition to smaller black and white photographs and drawings. I regret only that this text, like most others in the field, does not supply scales to each picture. Biology deals with structures over at least a millionfold size range. Certainly, beginners ought to be helped to some sense of scale. Volpe's book is directed at intelligent beginners. It is first rate overall and should stimulate both students and teachers using it.

The three other texts considered here are rather more like each other than not. Sherman and Sherman and Levy present material in a traditional manner, emphasising physiology and structures far more than genetics and evolution, though the latter subjects do make an appearance. The Shermans' book is clearly written, though the use of boldface to introduce important words and phases makes the text rather shout at the reader. I concede that students in this country often apply liberal amounts of yellow highlighting to achieve

the same result, but I would rather shout myself than be shouted at. The quality of drawings and photos is not as high in this book as in Volpe's, but the drawings especially are clear. The text begins with a discussion of the origin of life and the methods of science, considers cell architecture, biologically important molecules and cell energetics. The first section closes with a discussion of the chemical basis of heredity and of cell division. A long second section is devoted to development and physiology and this is followed by a shorter section on mendelian and population genetics. Overall, the book is workmanlike, but I did not find it especially exciting. Its design also made it difficult reading. The book is printed largely in shades of blue ink, including the text itself. This is hard on the eye.

Charles Levy's book, the only one of the four making its first appearance, is

similarly organised, but the bulk of the book considers physiology and regulation. Genetics and development are given only two chapters at the end of the text, about 60 pages out of about 550. I do not think that this balance is correct, but those who wish to emphasise human physiology may find the text useful. However, it should be noted that there are a number of errors of fact in both text and drawings. The creation of a text is a difficult job and I think that allowance for errors should be made. Bright students will catch many of them (for example the jump from calories to kilocalories that occurs from pages 57 to 58). Physically, the book is somewhat smaller than the two others already discussed and this cramps the illustrations, which are often deployed in the margins of the text. The audience for this book as for the previous text is the group of average college students. They can learn from both

books through diligent application, but I am not sure how interested they will be in either of these texts.

The last book to consider, by Mader, is directed at a less sophisticated audience than the other three. It is written in a simpler style and readers are talked at, rather than being shown the development of an idea. There is, from my point of view, an excessive catering to students' needs for information on, and concern with, drug action, and with venereal diseases. A large quantity of biological information is contained in this book. The author is trying to deliver it to students who may be preoccupied with matters other than classwork. I am not certain that the approach emphasising 'relevance' to society is the one to use. □

M. Edidin is Professor of Biology at the Johns Hopkins University, Boston, Massachusetts.

Primate cytogenetics

Dorothy A. Miller

The Phylogeny of Human Chromosomes. By Héctor N. Seuánez. Pp.189. (Springer: Berlin, Heidelberg and New York, 1979.) Paperback DM38; \$20.90.

CURIOSITY about the origin of man has led to the application to evolutionary problems of a variety of new techniques. *The Phylogeny of Human Chromosomes* by Héctor N. Seuánez deals with information derived from the use of the chromosome banding techniques that were developed during the past ten years.

The initial chapters present a brief overview of human evolution. This is useful as background, but the author fails to point out that chromosome studies can be carried out only on living organisms. Although we might like to know the karyotype of *Homo erectus*, comparisons must be made among species that exist at the present time. This volume, then, deals primarily with comparison of the karyotype of human with those of the great apes — chimpanzee, gorilla and orangutan. One of the results of comparative chromosome studies has been to place the gibbons and siamangs in a family separate from the great apes, with which they were classified at one time.

Brief descriptions of the major chromosome banding techniques are presented. G- and R-banding are used to identify every chromosome in the complement. (Q-banding is used for the same purpose, not just for identifying brilliant variant regions, as the author implies.) G-banded karyotypes of human, gorilla, chimpanzee (two

species) and orangutan are illustrated. Direct comparison of the various species would have been facilitated by presenting more composite karyotypes in which the presumptive homologues are placed side by side. It is unfortunate that the figures in chapter 7, where some of the chromosomes are placed together for comparison, are not arranged as effectively as are those in chapter 6 in which chromosomes of different orangutans are compared.

The most exciting finding in primate cytogenetics has been that every human chromosome has a recognisable counterpart in each of the four species of great apes. (This is in marked contrast to the results obtained in the rat and mouse, which are also evolutionarily related species but in which only a few chromosomes have similar banding patterns.) Some reorganisation of the genetic material has taken place during the evolution of the higher primates and man. There has been one fusion that results in the human having 46 chromosomes compared to 48 in the great apes. The most frequently observed differences between the chromosomes of the four species are the result of pericentric inversions, which involve a break on each side of the centromere of a chromosome, with rejoining of the inverted segment within the same chromosome. In a practical sense this has facilitated the comparative studies because single altered chromosomes are much easier to recognise than multiple reciprocal translocations. There is no evidence that the pericentric inversions which have become fixed in primate evolution have affected the activity of the genes on these chromosomes.

The demonstration that there are chromosomes with similar banding patterns in humans and great apes is of

much more trivial interest because these chromosomes often carry the same genes. Somatic cell hybrid methods have been used to show that one or more genes on almost every human chromosome has a counterpart on the purported ape homologue. In only one or two cases was a particular gene not carried by the chromosomes that had similar banding patterns in the various species. Similar comparisons with rhesus and African green monkey chromosomes show that genes carried by human chromosome number 1 have been associated with a chromosome segment having the same banding pattern for perhaps 35 million years.

The 18 and 28S ribosomal RNA genes are in a rather special class because they are present in hundreds of copies per cell rather than in 2 or at most a few copies per cell, as is true of most genes. Extensive redistribution of the rRNA genes has taken place during evolution. Most primates have these genes concentrated in a single site, but the orangutan has rRNA genes on 9 pairs of acrocentric chromosomes, the chimpanzee and human on 5 pairs (not all the same), and the gorilla on 2 (or 3) pairs.

Detailed comparisons are presented of the results obtained using methods that provide information about heteromorphic chromosome regions, many of which contain highly repetitive DNA sequences. Quinacrine-brilliant regions, for example, are found only in chimpanzee, gorilla, and human, and a quinacrine-brilliant Y is present only in the latter two species. Human satellite DNAs I, III and IV generally anneal to corresponding sequences on fixed metaphase chromosomes of each of the great apes, although to only a small extent in the orangutan. Human satellite II, on the other hand, anneals to gorilla and orangutan chromosomes but

not to those of the chimpanzee. If human satellite II-like sequences are present in the chimpanzee, they must be there in very small amounts, a finding that is supported by the absence of much 5-methylcytosine, a rare base which is abundant in human satellite II.

Dr Seuánez is at his best when describing his own studies with the orangutan, in which he has shown that animals from Borneo and Sumatra differ by a pericentric inversion (perhaps marking incipient species), but that each population is still heterozygous for a different complex

chromosomal rearrangement. In this volume he has included a wealth of information about a broad range of techniques. Students and those interested in primate cytogenetics will find the volume useful because it includes a large number of references, although a single reference list would have been easier to use than will be the separate list presented after each short chapter. General interest readers will probably be disappointed by the book because the broader aspects of phylogeny have been submerged in the sea of minute details. A final chapter drawing together

information derived from the various methods would have been a welcome addition. Most of the illustrations are well designed, but the chromosomes in some of the composite karyotypes are so small that they present little information. Unfortunately there are a large number of typographical errors which distract attention from the message of the text. □

Dorothy A. Miller is Assistant Professor in the Department of Human Genetics and Development at Columbia University, New York.

Basic molecular biology

G.C. Walker

Basic Molecular Biology. By Fred W. Price. Pp.497. (Wiley: New York, 1979.) \$20.50.

BASIC MOLECULAR BIOLOGY by F.W. Price is intended to be a suitable text for freshmen with a background in general biology and chemistry. The book opens with an extremely elementary introduction to basic chemical principles and then is divided into four main sections. The first section, which comprises almost half of the book, discusses primary through to quaternary structures of proteins, and the relationship of structure to function. One chapter provides a particularly clear general introduction to enzymes and others discuss topics such as fibrous protein assemblies and antibodies. The second section covers the structure of biomembranes and biological energy transducers. The third section covers the structures and roles of nucleic acids in the storage and expression of genetic information. A somewhat speculative chapter on chromatin structure is included. The final section is quite broad and considers the organisation of prokaryotic and eukaryotic cells.

In his preface, Price states that his approach is 'structural'. Indeed, almost every topic is introduced by a consideration of the relevant chemical and structural parameters of the molecule or assembly in question. Since the author has also intentionally minimised the attention paid to molecular genetics and protein synthesis, the book is much closer in many respects to a biochemistry text than to books such as *Molecular Biology of the Gene* (Watson; W.A. Benjamin: Menlo Park, California, 1976) or *Molecular Genetics* (Stent and Calendar; Freeman: San Francisco, 1978). In particular, while genetics is treated as a subject in one chapter, very few genetic experiments or

approaches are discussed elsewhere. Knowledge of basic organic chemistry is required throughout.

The book is clearly written and profusely illustrated. Occasional touches of humour help personalise the text. However, greater care in the relative emphasis given to specific examples would have improved the book. For example, several pages are devoted to the physical parameters of invertebrate oxygen-transporting proteins yet the discussion of ATCase in the section on allosteric enzymes is very short and has no illustrations. Other examples discussed, such as that of resilin, seem to contribute little to an introductory text.

Price also comments that, in writing an introductory text, he has resisted the temptation to delve deeply into certain exciting aspects of molecular biology. Nevertheless, I was disappointed that a number of the models discussed in detail seemed quite dated and were presented in an uncritical fashion, and also that such a recent book did not even allude to current topics such as recombinant DNA, DNA sequencing, the Ames test, or hybridomas. □

G.C. Walker is an Assistant Professor in the Biology Department, Massachusetts Institute of Technology, Cambridge, Massachusetts.

Views of enzymes

Dennis Piszkiwicz

Steady-State Enzyme Kinetics. By Stanley Ainsworth. Pp.255. (University Park Press: Baltimore; Macmillan: London, 1977.) \$17.50. *Enzymatic Reaction Mechanisms.* By C. Walsh. Pp.978. (Freeman: San Francisco and Reading, 1979.) \$29.50. *Principles of Enzymatic Analysis.* Edited by H.U. Bergmeyer and K. Gawehn. Pp.260. (Verlag Chemie: Weinheim, 1978.) \$25.90.

In the past two decades our understanding of the nature and properties of enzymes has grown at a prodigious rate. The availability of texts describing these advances is now catching up with this growth. In recent years we have been treated to a large and somewhat redundant supply of texts on enzyme kinetics and mechanisms, albeit of varying scopes, lengths and quality. Three recent and different approaches to enzymology are examined here.

Kinetics observes catalysis in the time scale in which it occurs. It is the most important and popular tool available for the elucidation of enzymatic mechanisms.

Steady-State Enzyme Kinetics by Stanley Ainsworth presents an up to date survey of the mathematical gymnastics used to analyse enzyme kinetic data. It emphasises the methods of deriving models that describe the orders and methods of interaction of substrates and effectors to the catalytic molecules. The major fault of this text is that it really does not address the purpose of enzyme kinetics — the definition of the mechanism of catalysis — in as much detail as possible. It barely touches on subjects such as kinetic evidence of enzyme-substrate intermediates, pH dependencies, and so on, which can be related to the bond-forming and bond-breaking steps. It is unsettling to realise how so much sophisticated analysis can yield so little understanding of the forces being studied. In a review of Irwin H. Segal's *Enzyme Kinetics* (Wiley: New York, 1975), a text of similar scope, S.E. Halford (*Nature* 259, 255; 1976) noted that enzyme kinetics is a tool of biochemical research, not an intellectual discipline in its own right. Even as a tool, Segal's *Enzyme Kinetics* is more detailed and more accessible than this newer volume.

The results of the efforts of legions of enzymologists are brought together in *Enzymatic Reaction Mechanisms* by Christopher Walsh. This text, as the author notes in his preface, developed from his

Atmospheric Physics

J. V. IRIBARNE and H.-R. CHO

1980, xii + 208 pp. + indexes
Cloth Dfl. 40,- / US \$ 15.95
ISBN 90-277-1033-3

Atmospheric Physics is an elementary and comprehensive textbook on the terrestrial atmosphere and can be used for second and third year university courses. The book requires only the basic understanding of mathematics and such knowledge of physics as can be acquired in most first year general physics courses. It can be used in two ways. Firstly, a general review of atmospheric physics is provided for students who work or plan to work in other fields (such as geophysics, geography, environmental sciences, space research), but are interested in acquiring general information. Secondly, it will serve as a general and elementary introduction for students who will later specialise in some area of atmospheric science. Each chapter is concluded with a list of questions and problems which will help the reader to attain a more detailed insight into the various subjects discussed.

P.O. Box 17, 3300 AA Dordrecht, Holland
Lincoln Building, 160 Old Derby Street,
Hingham, MA 02043, U.S.A.

own teaching, and it owes much to a course taught by his mentors R.H. Abels and W.P. Jencks.

The approach taken is to classify and present enzyme reaction mechanisms according to their chemical types: (1) group transfer reactions; (2) oxidation-reduction reactions; (3) elimination, isomerisation and rearrangements of substrate skeletons; and (4) the making and breaking of carbon-carbon bonds. This approach to organisation makes eminently good sense as it facilitates understanding of the basic patterns and principles underlying the reactions.

In presenting data which support the various enzymatic mechanisms, Walsh brings to bear evidence obtained from a wide variety of methodologies, including kinetic analyses, isotope exchange studies, protein chemistry, and the results of X-ray crystallography. The fundamentals of enzyme kinetics are presented, but they are treated superficially and are interspersed with discussions of various enzymes.

The grand scope of this text results in, at times, a superficial coverage of material pertaining to many mechanisms. It would have been preferable to have seen fewer examples of enzyme mechanisms examined in greater depth. Nevertheless, this original, ambitious work fills a need, and it is likely to be welcomed by both teachers and students of enzymology.

Principles of Enzymatic Analysis edited

by H.U. Bergmeyer and K. Gawehn is directed not toward the classroom but toward the laboratory. In this book enzymatic analysis means determination of the concentrations of substances with the aid of enzymes and determination of the catalytic activities of enzymes in biological materials. It is derived from a section of a larger work, *Methods of Enzymatic Analysis* by the same editor (Verlag Chemie and Academic Press, 1974), which has already gone through two editions. This revised version is a modest advance over its predecessor.

In this volume 20 authors have contributed to sections describing theoretical principles (including kinetics), the handling of biochemical reagents and samples, measuring techniques and instruments, and evaluation and assessment of experimental results. The derivation, content and format of this book will probably restrict its use to that of a reference work. As such the prospective user should be advised that it is limited in scope and often overly brief. This book is not intended for someone who wants to learn how enzymes function, but it may serve as a practical handbook for someone who is about to do his first enzyme assay. □

Dennis Piskiewicz is Associate Professor in the Department of Chemistry at Duquesne University, Pittsburgh, Pennsylvania.

Biochemistry for all occasions

Ernst Noltmann

Biochemistry: The Chemical Reactions of Living Cells. By David E. Metzler. Pp.1129. (Academic: New York, 1977.) \$22.50.

Modern Concepts in Biochemistry. By Robert C. Bohinski. Pp.600. (Allyn and Bacon: Boston, Massachusetts, 1979.) \$19.95

Biochemistry. By Frank B. Armstrong and Thomas P. Bennett. Pp.504. (Oxford University Press: New York, 1979.) \$19.95

Elementary Biochemistry, An Introduction to the Chemistry of Living Cells. By Julian Davies and Barbara Shaffer Littlewood. Pp.346. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$20.75.

WITH biochemistry having become a serious (?) topic of prime time television talk shows, including guest appearances by dignitaries such as Linus Pauling, it is not surprising that this popularity is also reflected in an annually increasing onslaught of new textbooks of bio-

chemistry which present a confusing choice to both the instructor and the student. A most telling testimony is perhaps also the fact that this reviewer was asked to render an opinion simultaneously on four different textbooks. An attempt will be made to comment on the four books in the order indicated above which is according to decreasing size but which also reflects an order of value as perceived by this reviewer.

Metzler's coverage of the field is current and thorough. It is supported by many good illustrations and by superb bibliographies for each of the sections. The emphasis appears to be fairly even and the decision of the author to include many fascinating applications of biochemistry in special boxes set off from the main text, rather than to incorporate them into the narrative flow of fundamental material, is of great help to the student whose academic programme may demand a judicious use of study time. The detail of Metzler's text is both an advantage and a disadvantage. It makes reading slow for the novice. However, the writing is good and the style interesting. Moreover, the sentences are varied and well constructed — something rare for a science text. Also, on re-reading, the detail does not appear to be excessive and the opportunity to pursue

details through the extensive, up-to-date bibliography makes the book a good reference source. Metzler's book is definitely designed for the serious biochemistry undergraduate major or graduate student. This reviewer would place it as a text besides or even ahead of such greats as "White, Handler and Smith", "Mahler and Cordes" or "Lehninger."

Bohinski's book is, in general, written in a clear fashion. Individual chapters, although beginning at the level of understanding for non-majors, proceed with great detail which sometimes overwhelms the student, who may have difficulty placing the information in the proper perspective. In our department, the text serves a one-quarter course for non-biochemistry science majors for which it was found to be a good background text because of its emphasis on structure-function relationships and on regulation as a key to understanding metabolism. It may be suitable also for a two-quarter course if students come with a solid background in biology and chemistry. Some definitions appear to be misleading. For example, this reviewer believes the explanation of quaternary structure (p.145) to be incorrect. The desire for completeness has led the author on occasion to use metabolic schemes too complicated to be didactically useful (for example, fatty acid synthesis). Some students feel that additional examples of problem-solving would be helpful for the understanding of pK_a 's, ΔE° , and the intricacies of peptide sequencing. Of all the four texts the print of Bohinski's book is the most difficult to read, especially when it appears in the italic mode. As a special point, this reviewer enjoyed the essay by Morowitz on the "Six Million Dollar Man" included in the Preface. It serves well to put it all in perspective.

The book by Armstrong and Bennett presents biochemistry at a level and with a degree of detail adequate for a service course for non-majors for whom biochemistry is more an ancillary requirement than a discipline of interest for its own sake. The coverage of the various biochemical topics varies and seems to be influenced by the preference of the authors. The chapter on biogeochemical cycles is unusual. The treatment of enzymes and nucleic acids is thorough. Repair and recombination of DNA are dealt with in a very up-to-date fashion. A separate chapter on nutrition is particularly valuable. In fact, it is most deplorable that this vital area of biochemistry is neglected by most textbook authors. Unfortunately, practically no mention at all is made of fatty acid synthesis, and synthesis, in general, is given little attention. Frequent reference is made to medical relevance which is usually of interest to students, including those who are not premeds. This reviewer liked the historical introduction as well as the

summaries after each chapter, the latter allowing students to place the various subfields of biochemistry in relation to each other.

Finally, *Elementary Biochemistry* by Davies and Littlewood is quite different from the other three books reviewed here. While the authors warn that the title may be misleading, this reviewer feels that the simplistic treatment may be just that, namely misleading. A treatment of enzyme kinetics without ever using the word "kinetics" or without mentioning Michaelis and Menten or Lineweaver and Burk appears to be less than "elementary". However, if perused only by those whose only aim is to get a "feeling" of biochemistry "for fun", it is a nice means to seduce perhaps the non-science

student to probe more deeply into what biochemistry really is. The descriptions of some biochemical techniques are very good and may induce those whose interests are aroused to look further. Interestingly, the problem sets provided by the author appear to be much more difficult than the text suggests. Students will need considerable help from the instructor and from teaching assistants in order to be able to solve them. Nevertheless, the book has a good format. It reads easily, the summaries are clear and, as a whole, the book may help newcomers to sense the excitement of "being in biochemistry". □

Basic chemistry

James Viers

Fundamentals of Chemistry. By Fred H. Redmore. Pp. 711. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$18.95. *A Basic Math Approach to Concepts of Chemistry.* By Leo Michaels. Pp.312. (Brooks Cole: Monterey, 1979.) *Fundamentals of Chemistry.* By E. Kostiner and J. R. Pea. Pp.472. (Harcourt Brace Jovanovich: New York, 1979.)

IN a foreword to *Fundamentals of Chemistry*, by Fred H. Redmore, the statement is made that the text was developed out of an attempt to expand and upgrade *Basic Chemistry* by Seese and Daub into a general chemistry text. I do not feel that either the expansion or the upgrading is sufficient to place *Fundamentals of Chemistry* into the category of a desirable general chemistry text which will properly prepare students for higher level chemistry. While most of the topics normally found in general chemistry texts are included here, the treatment of a number of topics is somewhat cursory. The kinetics chapter, for example, totals 11 pages (as does the chapter on co-ordination compounds) including summary, exercises and problems and a page of objectives. Perhaps the biggest shortcoming in the book is the number and type of end-of-chapter problems. The chapter on kinetics mentioned previously has only two exercises (of a qualitative nature) and three rather trivial problems. Other chapters do contain more problems many of which have multiple parts. However, almost all of the problems are basically of the drill and practise type, with few challenging ones and very little application of chemical principles to relevant or practical types of problems. An instructor who uses this text will very likely be forced to use

supplementary problems extensively.

There are a large number of general chemistry texts on the market today which are superior to *Fundamentals of Chemistry* for use in the main line course which is structured to prepare science and engineering students for organic and/or physical chemistry. If this text has a market, it might be in the introductory chemistry course currently offered as a year-long terminal course at many schools. The book is well written and very attractively designed in a two-colour black and red format. It can be recommended for those courses which are intended to be terminal and for a course in which the instructor wishes to present chemistry in a rather qualitative fashion.

A Basic Math Approach to Concepts of Chemistry, by Leo Michaels, is a workbook, basically of the programmed type, in which each unit is broken into parts and frames. Questions within each frame are designed to enable the student to master each idea before moving on to the next frame. The purpose of the text is purportedly to teach students who are taking or preparing to take a college course in chemistry the mathematical skills necessary for such a course. Some of the mathematical topics covered, however, border on the absurd for any student in college. Unit 1, for example, deals with the naming of whole numbers (example: Write the number that goes with the word name eight thousand). Unit 2 treats naming, adding, subtracting, multiplying, and dividing of decimal numbers, while unit 3 covers the definition, adding, and subtracting of signed numbers. Unit 4 teaches the student to write numbers in power-of-ten form and to multiply and divide numbers in power-of-ten form. It is inconceivable that any college student who has graduated from high school or even elementary school should need to review mathematical material of this nature. The remainder of the 14 units are devoted to topics which are somewhat more advanced and more directly related to calculations of

a chemical nature. These topics, however, are covered at a rather superficial level. The only type of student who is likely to benefit from this workbook is a student whose high school mathematical training is virtually nonexistent. If the student really needs exposure to many of these topics, it is very doubtful that he will be able to compete successfully in a true college level general chemistry course.

Fundamentals of Chemistry by E. Kostiner and J. R. Rea, is designed for a one term, preprofessional introductory chemistry in a straightforward, easily readable style. The book is attractively designed in a two-colour black and red

format which makes it very easy to read. Major topics found in most full year texts which are not presented here include: kinetics, thermochemistry, nuclear chemistry, co-ordination compounds and a discussion of the transition elements. A reasonably large number of worked-out example problems are included in most of the chapters as well as a fair selection of end-of-chapter problems. Fairly extensive chapters on organic chemistry and biochemistry (about 13% of the text material covers organic and biochemistry) are attractive features of the book and should appeal to the audience for which the text is designed. Historical and relevant

sidelights are prominently displayed throughout the text and also add appeal. The book emphasises the basic concepts of chemistry, however, and is not of the 'cutesy' variety with cartoon-type drawings which has recently become popular for use in the abbreviated one term general chemistry course. This text is highly recommended for instructors who wish to present a one term course in general chemistry which emphasises the basics of chemistry. □

Experimental organic chemistry

P.F. Schatz

Experimental Organic Chemistry. By David Todd. Pp.346. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$13.95. *Techniques and Experiments for Organic Chemistry*. Third edition. By Addison Ault. Pp.442. (Allyn and Bacon: Boston, 1979.) \$16.95.

RECENTLY, there has been a flood of organic chemistry laboratory manuals from the book publishers. Among these books are revised editions of previous manuals and a few brand new manuals. On perusing the manuals it is sometimes difficult to avoid a sense of *déjà vu*, for there is a great deal of overlap in the experiments detailed. One new book that does not suffer in this way is *Experimental Organic Chemistry* by David Todd. Although there are a few familiar faces, this collection of fifty-eight experiments contains many new experiments for the undergraduate. With this large number to choose from, an instructor should have no difficulty in selecting enough interesting and instructive experiments to fill an introductory organic laboratory course. Examples of common organic preparations, Grignard reaction, Friedel-Crafts acylation and Fischer esterification to mention a few, are included, as well as some not so ordinary preparations such as the Peckmann coumarin synthesis and the Rothmund reaction for the preparation of tetraphenylporphyrin.

Unlike many laboratory manuals, which present laboratory techniques separate from the experiments, Todd introduces the techniques as an integral part of a specific experiment. For example, column chromatography is explained and

demonstrated in an experiment on extracting pigments from spinach. As a consequence of this approach, one could be locked into doing a certain core of experiments in order to introduce the basic techniques. The experiments are detailed enough to be carried out by the inexperienced undergraduate student. The discussions of the techniques are concise and give enough information for the student to understand the how and the why of the techniques. The section on NMR and IR spectroscopy is very short (7 pages) and just covers the basics. This would not be the book for a laboratory course that is heavy on instrumentation.

Among the good points of the manual are the detailed instructions conveyed in a very conversational style. This, coupled with a section entitled "Most Common Errors", which appears after each set of instructions, should lead to good results for most students. Another favourable point is that many of the experiments and compounds encountered in the experiments can be related to familiar, naturally occurring materials. The NMR and IR spectra of thirty-five compounds are illustrated, but they appear to be retracings of spectra as opposed to reproductions of actual spectra (the coupling in the methyl triplet of the ethanol spectrum on page 97 does not appear to be symmetric as it should be). Also, the solvents used to prepare the NMR samples are not noted on the spectra.

There is some inconsistency in the warnings regarding hazardous properties of the chemicals. For example, the toxicity of benzene is noted in Experiments 25 and 33, but no mention of it is made in an earlier one — Experiment 13, the Grignard synthesis of monodeuterated benzene. Also in Experiment 13, 1,2-dibromoethane is suggested as a reagent for starting reluctant Grignard reactions and no warning is given regarding its toxicity. This compound is on the OSHA tentative Category 1 carcinogen list, as is benzene. Thus, any instructor using this book, or any other laboratory manual for that

matter, should check to see if the hazard warnings included need to be supplemented or updated.

Among the revised editions of organic chemistry manuals is *Techniques and Experiments for Organic Chemistry* by Addison Ault. This is an updated and expanded version of a good laboratory manual. Better than one-half of the book is devoted to describing techniques and apparatus for the organic chemistry laboratory. This is done thoroughly and clearly and is illustrated with large, accurate drawings. Modern spectroscopic techniques, NMR, IR, UV and mass spectrometry, are dealt with extensively.

The second half of the book is a compendium of experiments demonstrating the techniques and the characteristic reactions of organic compounds. The experiments are divided into four groups: separations, transformations (one-step procedures), synthetic sequences and projects. The separations, transformations and synthetic sequences are all well worked out, carefully detailed experiments which provide good working experience with organic chemistry.

For the more adventurous and skilled, there are the projects. These are procedures excerpted directly from the primary sources in the chemical literature. The compounds included are natural products, are theoretically interesting, or have unusual physical properties. The ability to reproduce procedures directly from the chemical literature is very important to the organic chemist.

In summary, Ault's book is a well written modern, informative manual that should be looked at seriously by anybody who is considering using laboratory manuals. □

Basic botany

Ralph S. Quatrano

Botany: A Brief Introduction to Plant Biology. By Thomas L. Rost, Michael G. Barbour, Robert M. Thornton, T. Elliot Weier and C. Ralph Stocking. Pp.344. (Wiley: New York and Chichester, UK, 1979.) \$20.15. *Plants: Basic Concepts in Botany.* By Watson M. Laetsch. Pp.510. (Little, Brown & Co.: Boston, Massachusetts, 1979.) \$17.95. *Instructor's Manual to Accompany Plants: Basic Concepts in Botany.* By Watson M. Laetsch. Prepared by Mary S. Manteuffel. Pp.121. (Little, Brown & Co.: Boston, Massachusetts, 1979.) \$17.95. *Instructor's Biology.* By Kingsley R. Stern. Pp.482. (Brown: Dubuque, Iowa, 1979.) \$13.95. *Laboratory Exercises/Biology of Plants.* Fourth edition. By H.L. Dean. Pp.326. (Brown: Dubuque, Iowa, 1978.) \$9.95. *The Green World, An Introduction to Plants and People.* By Richard Klein. Pp.512. (Harper and Row: New York, 1978.) \$14.95.

MOST recent textbooks of plant science that are aimed at beginning undergraduates can be grouped into two classes: those that approach the subject from a more traditional and classical manner, and those that popularise plants by emphasising their uses and values to society, that is, ethnobotany. The former tend to be used in courses for agriculture, forestry and biological science majors. Such courses usually serve as a technical framework upon which is based an advanced curriculum in morphology, physiology, ecology and systematics. The other texts began to appear during the last decade and tend to be used in non-major courses and in two-year colleges where exposure to plants, their diversity and value to society are stressed. The texts reviewed here represent a wide choice between these categories.

One of the best and more popular classical texts for majors by Weier *et al.*, *Botany*, has now been published in a shortened version, *Botany: A Brief Introduction to Plant Biology* by Rost *et al.* In many ways this text is a revision of the larger fifth edition (1974), since much of the subject matter has been rewritten and updated and new drawings and figures added. It is still a basic plant science text with no major change toward a more simplified or popularised treatment of the science. (Generally, the selection of topics to retain and condense was good, considering the difficult job of reducing a 642-page text to 344 pages (a slightly larger format, however).) The bacteria and virus chapters were dropped and extensive coverage of certain topics was reduced (for example, CAM metabolism and C_4 photo-

synthesis). However, all the basic botanical subjects are well represented in breadth and depth in the revision. The illustrations are excellent, especially the drawings. The basic organisation and groupings of topics are flexible; subject matter usually covered together can be assigned as units (chapters/appendices) rather than scattered pages. The one minor exception is the coverage of genetics where the molecular aspects of gene expression are covered within the chapter on metabolism separate from mendelian genetics. This is a well written text, with a good glossary, chapter summaries and a basic chemistry appendix. This text couples a sound treatment of the essential topics to be presented in an introductory plant science course with conciseness and brevity. It would be a good text in a short course for majors, the "plant" text in an Introductory Biology series and an alternative to a popularised treatment of plant biology for an introductory course at a junior or community college.

Laetsch has written a text for majors (*Plant: Basic Concepts in Botany*) that presents the traditional topics but in addition includes a considerable emphasis on the role, uses and importance of plants in the lives of students. His approach is to present topics in a context with which students are familiar and to stress the importance of plants in their lives. Energy is introduced in the first chapter within the broad framework of the biosphere which includes mention of food chains and energy transfer within ecosystems by use of common examples. This chapter and the following one entitled "Agricultural Revolutions" will impress on the reader the importance and usefulness of plants to their existence and the future of mankind. A fairly typical coverage of the plant kingdom follows in the second part of the text which exposes students to the diversity of plants. Taxonomic principles are covered using Angiosperms that everyone knows, that is, "the supermarket plants". This is extended in the Appendix (Supermarket Taxonomy) in which a brief taxonomic description is given for 16 selected families of popular dicots and monocots. The last chapter of this section deals with "People's Plants", in which 16 plants are presented in a historic and socio-economic framework to acquaint students with those "plants that keep our culture running" (wheat, sugar cane, rubber, coffee, tobacco).

These first two sections should serve to heighten the interest of the students to delve into the last two sections dealing with the structure/function and evolution of seed plants. Here the organisation of the material is similar to most other texts and will allow an instructor considerable flexibility in covering the basic and more popular topics in any sequence he desires and still be able to assign individual chapters. However, the depth in which most topics are covered (for example, photosynthesis/respiration and survey of

The chamber or spathe of the cuckoo pint traps flies carrying pollen from other plants, so aiding its fertilisation.

the plant kingdom) is not as extensive as in other texts for majors such as (*Biology of Plants* by Raven, Evert and Curtis). Little chemistry is included (no structural formulae) and hence the freshman with no chemistry background would have few problems with this text. The author has introduced basic botanical principles in a way that will stimulate the student's interest and excitement in the plant sciences. The text is well written and includes extensive references, chapter summaries and review questions, a glossary, as well as 1-2-page supplements scattered throughout the book. These add more depth and help explain abstract concepts that might interfere with the flow of the text. A helpful *Instructors Manual* is included. The text is different from others now on the market but in a way that does not eliminate its use in any traditional plant science course or in a non-major course. I suspect this text can be adopted by a wide range of existing courses at different types of educational institutions.

The text *Introductory Plant Biology* was written by Kingsley R. Stein to "emphasize current interests (of students) without giving short shrift to botanical principles". Stern's approach is that the basic science of botany is more meaningful to beginning students if its relationship to the more applied fields (for example, horticulture) is emphasised. This text, like the one by Laetsch, falls between the two extremes of introductory plant texts. For the most part, the integration of applied botany into the main part of the text does not constitute much more of an emphasis than most other traditional texts. However, 90 pages of Appendices represents most of the emphasis on practical botany. This includes a section on the use of biological controls as an alternative to chemical control by pesticides and herbicides, a

From *Color in Plants and Flowers* (Everest House: New York, 1978)

listing and brief description of useful plants (for example, wild edible plants, poisonous and medicinal plants), home gardening tips and information about conditions for optimal growth of common houseplants. Also included in the Appendices, however, is a section with more details of DNA structure and function, photosynthesis and respiration for those who wish a more in-depth treatment. The first 10 chapters of the text represent the areas of morphology, physiology, development and genetics while the remaining 11 chapters deal with classification, ecology and a survey of the plant kingdom including bacteria, blue-green algae and viruses. One of these chapters, entitled "Flowering Plants and Civilization", discusses 15 well known families and, using representative examples of each, Stern briefly describes their ties with various cultures as well as their economic importance.

Review and discussion questions follow each chapter as well as a glossary at the end of the text. A well illustrated and proven (fourth edition) lab manual is available from the same publishers (*Laboratory Exercises. Biology of Plants* by H.L. Dean). Although this book can be used in major courses, the depth and level of coverage of topics plus the nature of the Appendices suggest a probable wider acceptance in the non-major or non-science courses.

The *Green World. An Introduction to Plants and People* by Richard Klein is clearly different from the above texts. It is a unique contribution to botanical books and represents the opposite end of the spectrum from traditional, technical texts. His approach is clearly a historical one in presenting plants as an important component of various cultures. The author's view point is that "through an examination of the green world we can better understand the modern world and

the civilization from which western culture has evolved". With this objective his text is quite successful. He presents fascinating and exciting historical and cultural facts about plants that will no doubt interest any reader. Chapter titles include Economics and Politics of Food, Plants in Religion, Medicinal Plants, and subheadings such as Spices and Savory Herbs; Plants of Superstition, Myth and Ritual; Herbs, Herbals and Herbalists; and Botany of Coffee. It is not a popularised or strictly applied text but more of a scholarly, intellectual presentation of the role plants have played and will continue to play in society. It is flavoured with the personality of the author which is quite refreshing. However, the coverage of the topics normally found in the classical texts is brief and simplified and mainly confined to scattered one- or two-page essays or supplements to the major chapters. Conspicuously absent are coherent sections on morphology, mendelian and molecular genetics, survey

of the plant kingdom and respiration to name a few. With the exception of a few references at the end of chapters, there are none of the usual aids such as chapter summaries or review questions and a glossary. I doubt if this book will be used as the sole text in a beginning botany course for science majors. It would have merit as supplemental reading in such a course, in a non-major course, or as a text in a seminar course for advanced botany majors interested in a different and valuable perspective.

Instructors of plant science have quite a diversity of good new texts from which to choose the vehicle to convey the science and excitement of botany to young, eager minds. □

Ralph S. Quatrano is Professor of Botany and Instructor in General Botany courses at Oregon State University, Corvallis, Oregon.

Vertical section through the sorus of the fern, *Dryopteris*, showing sporangia in various stages of development.

From *Intermediate Botany* (Macmillan: London)

Modern virology

General Virology. Third edition. By S.E. Luria, James E. Darnell Jr, David Baltimore and Allen Campbell. Pp.578. (Wiley: New York and Chichester, UK.) \$23.50.

THIS excellent textbook uniquely fills a major need in the biological sciences: a single volume to introduce the many facets of modern virology. It is clearly written and well organised, so that it can be used essentially as the sole reference source for a general virology course.

As expected from the credentials of the authors, the book heavily emphasises the

P.C. Kimball

molecular level of knowledge about viruses. To take full advantage of this text, students should have had some previous exposure to the basics of molecular biology from a biochemistry or genetics course (or both). Certain chapters summarise the principal features of gene expression and animal cell biology; however, as indicated by the authors, these helpful reviews cannot substitute for a more thorough treatment of these topics prior to using the text. Some previous exposure to advanced mathematics, especially an introduction to statistical concepts, would also be useful to the students. Thus, this text is recommended primarily for advanced

undergraduates or graduate students majoring in the biological sciences. To read the entire text in one academic quarter will be an intense experience for such students; those in the semester system will still find the breadth and depth of material challenging. For these reasons this text is not recommended for an introductory course for less advanced undergraduates or those not majoring in a molecularly orientated programme; unfortunately, no text suitable for these latter students is presently available to provide the same broad coverage of the field on a more introductory level.

The book is well documented with an 80-page bibliography. Therefore, it will continue to serve the students as a detailed reference book. Although important new developments are frequent in virology in

this age, the text is thoughtfully written to prevent rapid obsolescence. For example, the book went to press just before the first convincing demonstrations that RNA splicing is required for production of mRNA in several mammalian systems. Nevertheless, the background for this finding is carefully developed in discussions on the relationship between cellular hnRNA and mRNA, and in the summaries of known details of viral mRNA production. In fact, the authors correctly predicted that the adenoviruses would be one of the most productive systems for clarifying precursor-product relationships in mammalian mRNA

synthesis. In general, where significant controversy exists, the authors present a balanced view and try to indicate the experimental approaches most likely to lead to resolution of the issue. Another strong point is the thorough description of most virological methodology in frequent use today.

The one major deficiency of this text for some purposes may be the relative lack of emphasis on the overall effects of viruses on the host, especially in higher organisms. Thus, the nature of viral diseases and defence mechanisms in animals are given only summary treatment, while there are only hints of the importance of plant and

insect pathogens for agriculture. Many students continuing their education in the biological sciences may encounter some of these topics in other specialised courses, depending on their interests; but some teachers may wish to supplement the text in these areas for the sake of providing greater appreciation of the more biological aspects of virology, to complement an otherwise complete introduction to the field. □

P. C. Kimball is a Molecular Virologist working at the Ohio State University Cancer Centre, Columbus, Ohio.

Basic biology of malignancy

Joseph R. Bertino

Fundamentals of Oncology. By Henry C. Pitot. Pp.192. (Marcel Dekker: New York, 1978.) \$9.95.

THIS concise textbook, which stems from a course given at the McArdle Institute for Cancer Research at the University of Wisconsin, is directed toward non-physician scientists, undergraduate and graduate students, and postdoctoral fellows in the biomedical sciences. Actually, medical students would also find in the book a great amount of material not covered adequately in their courses in pathology and medicine.

Since the book is written by one author, the writing is consistent throughout, and the 12 chapters are all equally well done. The author writes in a lucid direct style, and is able to present the reader with the important aspects of each topic with sufficient definition and background so as to be easily digested. Each chapter is referenced; the student who wishes to read in more depth on a particular topic will find all of the key references. The titles of articles are included, so that although the text is not documented (which would diminish its readability) the appropriate references for each section can be found. The author is an experimental pathologist and biochemist, and I found the chapters on aetiology and pathogenesis of cancer, and the biochemistry of cancer especially well done. Since these chapters comprise most of the message, the book is very successful. Other textbooks may contain

more information on specific topics, but none present so much information in such a well written, concise fashion.

The book does not cover topics such as cancer diagnosis or cancer treatment (chemotherapy, surgery, immunotherapy and radiation therapy), but the student who masters the material in this book will have the background to understand these more clinical topics.

In summary, this book is highly recommended for both undergraduate or graduate students as well as physicians who wish to know more about the basic biology of malignancy. □

Joseph R. Bertino is American Cancer Society Professor of Medicine and Pharmacology at Yale University School of Medicine, New Haven, Connecticut.

History of biology

Dov Ospovat

A History of the Life Sciences. By Lois N. Magnier. Pp.489. (Marcel Dekker: New York, 1979.) \$23.50.

LOIS MAGNIER'S *History of the Life Sciences* was written as a textbook for undergraduate courses in history of biology (it does not pretend to encompass the history of medicine). The discussion effectively begins with the pre-Socratic philosophers and continues into the "post Watson-Crick period" in the study of genetics. Some 70 pages are devoted to ancient and mediaeval science and another 40 pages to the Renaissance and Scientific Revolution. Most of the remaining three-quarters of the book treats the development of embryology, cell theory,

microbiology, physiology, and evolution from the seventeenth century to around 1900. Only in the last two chapters, both of which are concerned with genetics, is there any sustained discussion of twentieth-century biology. Scientific societies and microscopes are each accorded a brief chapter. There are some curious omissions. For instance, little attempt is made to relate seventeenth and eighteenth century biology to the Scientific Revolution. In the chapter on physiology Helmholtz is only mentioned, while Ludwig and Du Bois Reymond are completely ignored.

Magnier's basic technique is as follows: under each chronological or subject heading, she discusses the individual scientists deemed to have contributed to the advance of biology. One result is that many key issues — such as the philosophical and religious concerns of seventeenth, eighteenth, and nineteenth century biologists, and the arguments amongst nineteenth century naturalists and physiologists over appropriate styles of

explanation — are inadequately treated, in a piecemeal fashion in the biographical sub-sections.

The biographical approach is no doubt convenient for author and students. Likewise, because it conforms to the pre-conceived notions of most undergraduates, presenting science as progressing toward the present is perhaps the easiest way to teach the history of science. But since it is now pretty generally agreed that this is a wholly unsatisfactory way of understanding the past, it is strange to see it adopted as the organising principle of a new textbook.

Magnier often seems to be interested chiefly in whether a scientist was 'progressive' or 'retrogressive', as defined by mid-twentieth century knowledge and attitudes. Thus we are told that "although preformation theory impeded progress in embryology, it had one virtue. Preformationists generally rejected spontaneous generation" (page 188); that La Mettrie "paved the way for more

modern biological theories" (page 307); and that the *Origin of Species* was "a clear statement of the fact and mechanism of evolution and was quite convincing to readers with open minds" (page 385). Rather than attempting to present Haller's thought in its eighteenth century context, Magner praises him for his "restrained and modern spirit" (page 305).

The most serious weakness of the book is that Magner has made very little use of recent scholarship. As a sub-field of the history of science, the history of biology has come into its own in the last 20 years, yet Magner relies largely on much older works, predominantly books. Consequently, the presentation is often seriously deficient, given the current state of historical knowledge. This is especially true of the chapters on microbiology and biogenesis, evolution, and embryology.

I found numerous errors, some minor, others serious: the Reign of Terror is said to have occurred in 1789 (page 361); the relationship of von Baer's laws to the theory of recapitulation is mis-stated (page 204); the word 'biology' is said to have been coined as a replacement for 'natural philosophy' (page 405); and it is claimed that "taken as a whole" Buffon's writings "contain all the elements of the Darwinian synthesis" (page 358). □

Dov Ospovat is an Assistant Professor of History at the University of Nebraska, Lincoln, Nebraska.

Historical and physical geology

Hermann W. Pfefferkorn

Earth History and Plate Tectonics: An Introduction to Historical Geology. Second edition. By Carl K. Seyfert and Leslie A. Sirkin. Pp.589. (Harper and Row: New York, 1979.) \$18.95. *Geological Evolution of North America.* Third edition. By Colin W. Stearn, Robert L. Carroll and Thomas Clark. Pp.556. (Wiley: New York and Chichester, UK, 1979.) \$25.90. *Interpreting the Earth.* By Robert R. Compton. Pp.554. (Harcourt, Brace Jovanovich: New York, 1977.) \$16.95. *Physical Geology.* By L. Don Leet, Sheldon Judson and Marvin Kauffman. Pp.490. (Prentice-Hall: Englewood Cliffs, New Jersey, 1978.) \$24.25. *Physical Geology.* By Bob F. Mallory and David N. Cargo. Pp.538. (McGraw-Hill: New York, 1979.) \$16.95.

OUR understanding of the history of the Earth has changed dramatically with the appearance of plate tectonics as the unifying theory of geology. This change had to influence the teaching of historical geology profoundly. In pre-plate tectonic times historical geology was taught as a survey of local lithostratigraphies with endless lists of stratigraphic names, as a survey of the evolution of life, or ideally as a combination of both. The large number of lithostratigraphic names often made historical geology an exercise in memory. With the change in emphasis from acquisition of encyclopaedic knowledge to understanding geological concepts, many geology departments dropped undergraduate courses in historical geology. However, plate tectonics has given us a theoretical framework for the physical aspects of historical geology and simplified explanations for many geological phenomena. Thus, historical geology can now be taught with an emphasis on principle rather than detail. The first two books are examples of this new approach.

Seyfert and Sirkin present principles in the first seven chapters in 148 pages (evolution, geologic time, ancient environments, correlation and facies, plate tectonics). One chapter is devoted to cosmology and origin of the Earth. Chapters 8 to 14 (387 pages) deal with historical geology proper. Each of these chapters treats a large time interval like the Precambrian or late Palaeozoic. Only the last two chapters, on the Tertiary and Quaternary, are devoted to one period each. The Phanerozoic time scale and an extremely brief description of animal and plant groups are presented in Appendices A and B. Seyfert and Sirkin emphasise the history of North America but also treat the

rest of the world. Text figures are numerous and well selected. The maps of continent positions at different times are shown in an ingenious projection. Many maps and cross sections were apparently created or modified for this book and are easy to understand. The history of life is well integrated with the other aspects of historical geology.

Stearn, Carroll and Clark begin their book with a discussion of plate tectonics in Chapter 1 followed by seven chapters (147 pages) on principles (orogenesis, stratigraphy, correlation, time, cosmology, palaeomagnetism, evolution). The following chapters (377 pages) are grouped into four parts; the craton, the Cordillera, the Appalachians, and the Arctic and Cenozoic Ice Age. The discussion is restricted to North America and each part of the continent is taken as an example of one geotectonic province. For each area the geological history for the most significant time interval is given. Thus, some geological periods are treated more than once. An appendix gives concise descriptions of plant and animal groups. The book contains many excellent figures. I find it refreshing to see numerous figures from Canadian sources, which are not often used to illustrate textbooks. Graphs are well executed and two-colour printing improves clarity.

Both texts have about the same number of pages, use the same space for introductory chapters and main body, and are equally well suited to teach historical geology. Both make fascinating reading. The difference lies in their approach: time sequence with world-wide coverage (Seyfert and Sirkin) versus a case history of North American geological provinces (Stearn, Carroll and Clark). On the undergraduate level, historical geology has usually been taught as the second geology course after physical geology. The books discussed are written for just that sequence. However, while plate tectonics has unified many seemingly disparate aspects of historical geology, moving plates in ever changing configurations are a formidable matter for undergraduates to master so early in their geological education. Therefore, it might be more appropriate in the future to teach historical geology as a higher level course in the senior year. Both books could be used for such a course with some supplemental reading.

The other three books are all intended as an introduction to geology. They achieve this in different ways. Compton starts to analyse a certain area and to discuss the geological principles active there. The other two books follow a more classical approach. Leet, Judson and Kauffman begin with internal processes of the Earth and Mallory and Cargo with external ones. The surface processes are, of course, more familiar to the student and Mallory and Cargo have developed the most coherent sequence of chapters of the three books.

Two International Journals IMAGERY and REMOTE SENSING including CLOSE-RANGE PHOTOGRAMMETRY/ IMAGERY

Here is a highly topical and practical journal with a difference. The new-style approach will enable subscribers to enjoy, in easily understood magazine-type text, reading about all the international developments in these highly specialised technologies, the people behind them, and all those specialists who apply their skills to interpret the imagery produced from the complex instrumentation systems. In addition more conventional academic-type research articles and reviews in both theoretical and practical aspects will be included, with particular emphasis on interpretation.

Beside the conventional fields to be covered, such as geology, hydrology, forestry, etc. this journal will include natural disaster investigational reports, image transmissions from extra-terrestrial probes, satellite/avionic tracking and optical imaging systems, thermal imagery, military applications in peace and war, and aerial/underwater archeology.

Initially 5 issues a year; A4 format.
Subscription: £43 one year, 20% discount 2 years,
30% discount 3 years.

IMAGERY and REMOTE SENSING ABSTRACTS

This will cover the same fields as the main journal (but excluding the Close-Range Imagery Supplement) with an initial output of some 5,000 abstracts in over 1,000 pages.

5 issues. Subscription: £97 one year, 20% discount 2 years, 30% discount 3 years.

Their book is further written in a language which is easy to read. All the figures are easy to understand and many of them are original. In summary, the text by Mallory and Cargo can be used well in a course with many non-majors. Leet, Judson and Kauffman's book is written for science majors and geology majors. It is well written, rather complete in its coverage and gives extremely instructive examples and case histories. The photographs of outcrops and landscapes are impressive. Graphs are easy to understand and well done. Compton integrates principles with the discussion of specific areas and examples of scientific studies. He begins with surface processes and situations which

have not only geological but also environmental significance. This is clearly the most original of the three textbooks discussed here. A course based on this book might motivate students of geology who might be turned off by other textbooks. The colour photographs of outcrops, rocks and minerals would be especially helpful in a course without a laboratory part. Nevertheless, the data presented are detailed enough for the highest level introductory course.

In each of these three books I found some graphs and explanations similar to the ones I use in teaching. Selecting one of the three as a textbook would be a difficult choice. The decision would partly be based

on the kind of students who would predominate in the class. The other consideration would be how much one would be willing to adapt the course to the textbook. Compton's book would be best suited if course and textbook would coincide in the sequence of their treatment of topics. Leet, Judson and Kauffman's book could most easily be used in a course with a totally different sequence of lectures. Mallory and Cargo's book stands between the two others in this respect. □

Hermann W. Pfefferkorn is Associate Professor of Geology in the Department of Geology, University of Pennsylvania, Philadelphia.

Igneous petrology

S. A. Morse

The Interpretation of Igneous Rocks. By K. G. Cox, J. D. Bell and R. J. Pankhurst. Pp.450. (George Allen and Unwin: London, 1979.) Hardback £18; paperback £8.95.

AFTER half a century of near-starvation, students of igneous petrology are being presented with a succession of books that pay serious attention to phase diagrams. This book furnishes a square meal, devoting to phase diagrams more than thirty per cent of the text. And, joy of joys, at last we have a decent treatment of trace elements and isotopes, which occupy fifteen per cent of the text. The remaining half, liberally sprinkled with boldface where definitions occur, is taken up with such matters as intelligent classification, variation diagrams, fractionation, a respectable amount of petrography, experimental and controversial studies of natural rocks, volcanology, and plutonology (complete with flow equations). Appendices include directions for norm calculations and for plotting rock analyses in O'Hara diagrams. Exercises after each of the fifteen chapters are furnished with answers at the end of the book.

These blessings are not unmixed. Much space devoted to hypothetical phase diagrams could more usefully have been allotted to additional real ones with equivalent lessons as to their use. The quaternary projections may be overdone. The geometry of fractional melting is given short shrift, and its quantitative possibilities are mistakenly denied. Many readers will groan to find an unhappy treatment of variance which yields univariant points and divariant lines in 1-atm phase diagrams. Contrary to the

implications in the text, the isobaric restriction does rigorously reduce the variance by one, and this pitfall of nomenclature could have been avoided by use of an appropriate notation, such as F_p , to denote the restriction. Most of the classical phase diagrams are taken directly from the ancient literature without revision: we find albite melting variously at 1,120°C and 1,100°C rather than 1,118°C as determined by Greig and Barth in 1938. Kushiro's revision of Di-An-Ab is ignored except for being mysteriously ascribed to An-Ab. The incongruent melting of fayalite is not mentioned, nor is there any discussion of the role of oxygen in igneous fractionation. Carnegite is said to "exsolve" on a reaction loop.

But one should not look a gift horse in the mouth. The text focuses on methodology and is offered to petrologists

of all ages. As an unintentional test of its utility, the review copy was thoroughly consulted, marked up and leaned upon during a recent seven-hour research conference, and it gave good service. The treatment of trace elements in the mantle and in magmas, and of radiogenic and stable isotopes, is a masterpiece of concise, clear erudition. Mantle isochrons and hydrothermal Taylor engines are not neglected. The text is plainly written throughout and easily accessible to students. In sum, this book is a most refreshingly welcome and, indeed, indispensable addition to the still pitifully small genre. □

Chestnuts of the '40s

Brian J. Skinner

Exploration and Mining Geology. By William C. Peters. Pp.696. (Wiley: New York, 1978.) \$26.50. *Economic Mineral Deposits.* Third edition. By Mead L. Jensen and Alan M. Bateman. Pp.593. (Wiley: New York, 1979.) \$28.75.

THE generation of mining and exploration geologists trained during the 1950s had the delightful experience of reading H.E. McKinstry's eloquent volume *Mining Geology* (Prentice-Hall: Englewood Cliffs, New Jersey, 1948). There were no successors to inspire students of the '60s and '70s, but it is probable that William Peters' new book *Exploration and Mining Geology* will fill the role for the generation of the '80s. The need for a successor to

McKinstry's volume has become acute; the profession has grown enormously as mineral production has increased; mining methods have become more complex; many new techniques of geochemistry and geophysics have been added to the modern prospector's arsenal; the sophistication of geological information has grown dramatically and the economic conditions of today are far removed from those of the 1940s when McKinstry wrote his book.

Peters does not share McKinstry's mastery of English and his wry wit but he has prepared an admirable volume that the advanced student will find both pleasant and informative to read and that will also serve as a reference for the practising geologist. Throughout, he emphasises the observational and practical while at the same time urging the reader to keep an open mind. With good reason; new ways of looking at old ideas have found a lot of ore. The heart of the book, and the place where Peters' extensive experience shines through, is a nine-chapter section discussing what mining and exploration

geologists do and how they go about their business. But there are also concise and authoritative discussions of the origins and distribution of mineral deposits, of the engineering and economic aspects of mining plus descriptions of the way exploration programmes are organised and prospects evaluated. The volume is a mine of information and a pleasure to read.

How appropriate it would be to measure equal enthusiasm for the latest edition of another chestnut of the 1940s — Bateman's *Economic Mineral Deposits* — the book so many of us studied before we read McKinstry. When Bateman died in 1971, he had already started revising the volume. Perhaps he had delayed so long because the task of a total revision was beyond him; possibly he realised that the format of the volume, which dated back to the teaching pattern of his mentor, J.D. Irving, had become too cumbersome. Whatever the reason, when he did realise the task was beyond him, he asked his friend and protégé M.L. Jensen, formerly at Yale, now at the University of Utah, to complete the task. It was, in reality, a request to fit an old but successful format to a very different and rapidly growing field.

The experiment has not been entirely successful. The earlier editions were successful because they were a mass of reliable and carefully checked observations. When complex ideas were included (rarely) they were carefully explained. The present edition has the same broad coverage, the same mass of data and observations (some unchanged from earlier editions), but it is no longer reliable. Mistakes appear on many pages, especially where new material has been added. Many of these errors are minor to be sure, but they are, nevertheless, misleading and greatly reduce the value of the book for the beginning student. For example, the caption for Fig. 15-2 (a P - T diagram for the polymorphs of Al_2SiO_5) mentions "phase boundaries indicated by short dashes" as being not experimentally determined, and "longer dashes" being an extrapolation of the kyanite-sillimanite curve. But all boundaries shown are solid lines and in addition the reference used (Morey, 1964) is hardly the most recent or most authoritative. Even if mistakes are corrected in later printings though, the book introduces so many ideas, concepts and ways of plotting data without adequate explanation, that it is no longer the easily accessible volume that earlier editions were. The volume can probably be used as a class text (and presumably will be, because it has a broader coverage of topics than any other English language introductory text), but it will require very careful checking by the instructor and a lot of back-up information. □

Brian J. Skinner is in the Department of Geology and Geophysics at Yale University, New Haven, Connecticut.

Instrumental analysis

J.F. Coetzee

Instrumental Analysis. By Henry H. Bauer, Gary D. Christian and James E. O'Reilly. Pp.832. (Allyn and Bacon: Boston, Massachusetts, 1978.) \$23.95.

THE explosive growth of chemistry is making it increasingly difficult to decide which material should be included in the curriculum. It is also making it increasingly difficult for one or two authors to produce a uniformly authoritative textbook, particularly at the higher levels. This is certainly true of textbooks on instrumental analysis, because instrumentation is developing at an ever-increasing rate and this is occurring in a variety of essentially unrelated areas. The answer is to employ as many authors as are necessary to ensure authoritative treatment of all topics included. Any unnecessary proliferation of authors should be avoided, however, because it would create unnecessary editorial problems in achieving the reasonable consistency in approach, emphasis, style and other matters required for a pedagogically effective textbook. The compromise reached in the present text many not be ideal in that the 24 chapters have been contributed by 26 authors. Six chapters have two authors each, and only three chapters have been written by authors who have also contributed another chapter. Considering this plethora of authors, the undoubtedly odious editorial task has been performed well in most cases, however. Two introductory chapters, one to electrochemical methods and another to

spectroscopic methods, contribute significantly to the effectiveness of the text; a third, on separation theory, would have been a useful addition.

The balance of topics included in a textbook such as this must reflect to some extent the personal bias of the editors, but this reviewer finds it entirely reasonable. The three main subdivisions of instrumental analysis — spectroscopic, electrochemical and separation methods — are treated in approximately 350, 140 and 110 pages, respectively. Other topics make up the remaining 200 pages; among these are particularly useful chapters on computers and automation. An additional chapter, dealing with a critical comparison of trace analysis techniques, would have been welcome. The emphasis throughout is on instrumental methods of quantitative analysis, rather than on electronics and instrument design. No laboratory exercises are included. The rationale for these editorial decision to make the theoretical background of each method "as brief and qualitative as possible consistent with clarity and accuracy," but instructors who wish to strengthen these parts of the text can easily do so. An adequate number of questions and problems are included with the majority of chapters, but future editions of the text would benefit from the inclusion of a few more truly challenging problems and, of course, correction of some errors in the answers provided.

In summary, this text has major strengths and only comparatively minor weaknesses. It represents a new and basically sound departure in producing a textbook on instrumental methods of analysis, and it should be on the short list of anyone considering such a text. □

J.F. Coetzee is Professor of Chemistry at the Division of Analytical Chemistry, University of Pittsburgh, Pennsylvania.

General chemistry

Jerry A. Bell

Chemistry: An Introduction. Second edition. By Sydney B. Newell. Pp.563. (Little, Brown and Co.: Boston, 1980.) \$15.95. *Problem Exercises for General Chemistry.* By G.G. Long and F.C. Hentz Jr. Pp.364. (Wiley: New York, 1978.) \$9.80.

THIS is an outstanding, short text that fulfills the author's purpose, "to provide beginning students and their instructors with a comprehensive, understandable, and motivating introduction to chemistry."

The book begins with a simple, descriptive picture of the atom, to make the four succeeding chapters on stoichiometry,

naming and equations, comprehensible. It goes on to atomic structure, periodicity and chemical bonding in more detail as the background for material on states of matter and chemical change (solutions, equilibria, electrochemistry and rates) as well as brief introductions to nuclear, organic and biochemistry.

Although mathematics is used throughout, the text is suitable for students that have difficulty with quantitative reasoning; most concepts are introduced by homely and timely examples that involve relatively little mathematics and jargon, there are exceptionally clear appendices on working with numbers and units, and all examples are worked out in

1st Announcement

Vth Symposium: HORMONES AND CELL REGULATION

(from 01/10/1980 to 04/10/1980)

Bischenberg (near Strasbourg — France)

Sponsored by:

"Institut National des Sciences et de la Recherche Médicale" and the "Direction Générale à la Recherche Scientifique et Technique".

Organized by:

J.E. DUMONT, J. NUNEZ, B. JEANRENAUD, R.M. DENTON, F. MOREL, H.J. VANDERMOLLEN, G. SCHULTZ, B. HAMPRECHT

MAIN TOPICS

- Mechanism of steroid and thyroid hormone action
- Insulin action and neural control of its secretion
- Control of ovulation
- Regulation in cell culture and gene expression
- Peptide neurotransmitters
- Gut hormones
- Internalization of peptide hormone

As an International Cyclic Nucleotide Conference is to be held in Brussels in 1980, cyclic nucleotide and calcium regulation will not be treated at this meeting.

Preparations:

General lectures by invited speakers and posters with specialized sessions of poster discussion. The following speakers are already scheduled:

G. SATO (La Jolla), H.R. LINDNER (Rehovot), R.A. FLAVELL (London), J.J. VANDERHAEGEN (Brussels), U. GEHRING (Heidelberg), E. MILGROM (Paris), J. MESTER (Paris), T. HALLINAN (London), A. CARRUTHERS (London), G.J. DOCROY (Liverpool), J. BERNAL (Madrid), J.L. CARPENTIER (Genève), A. STEFFENS (Haren), A. LE CAM (Bethesda, Nice)

Abstracts with registrations should be received before June 1, 1980. General attendance will be limited to 100.

Forms can be obtained from:

Professor B. JEANRENAUD
Laboratoire de Recherches Médicales
Université de Genève
Avenue de la Roseaie, 64
1205 GENEVE
SUISSE

A few fellowships covering fee and eventually lodging and accommodations, will be available for participants who request it with justifications.

Oxford University Press

A Survey of Numerical Methods for Partial Differential Equations

Edited by I. Gladwell and R. Wait

This book gives users of numerical methods in industry, research establishments, and education a practical and theoretical account of the subject. Emphasis is placed on the description of viable numerical methods, and background theory is discussed in justifying their use. Topics discussed include finite-element methods for elliptic and parabolic equations, techniques for the solution of free and moving boundary problems, characteristic and finite-difference methods for hyperbolic equations, and methods for elliptic-hyperbolic equations. £13.50

Ideas of Space

Euclidean, non-Euclidean, and Relativistic
Jeremy Gray

This book is about mathematics: what it is and how it has been done. It discusses Greek and modern geometry, and goes on to discuss Einstein's theories of relativity, both special and general, and modern ideas of the shape of the universe. It is largely historical and chronological. This approach restores to the subject a mathematical richness lacking in other accounts. £12.50

Thermoluminescence Techniques in Archaeology

S. J. Fleming

Thermoluminescence has numerous applications: in medicine, in radio-chemistry, in personal protection at nuclear establishments, in geology, and in the study of ancient pottery. This book is the first to present the fundamental physical concepts of thermoluminescence together with many important examples of the construction of chronologies from various parts of the world. Recent research that has extended the scope of the thermoluminescence dating to cover ancient bronzes (using the ceramic-like casting-core that many of them contain) and the authentication of ceramics is also presented. Illustrated £15.50

Thermal Conduction in Solids

R. Berman

'Every now and again one happens gratefully on a monograph born purely of the author's desire to communicate, to distil the fruits of a lifetime's personal interest and research into a form which renders the topic accessible to a wider audience. This is just such a book . . . being a gifted expositor, he is particularly well fitted to convey to others some of his continuing fascination with this technologically important subject.' *Nature*. This important book, first published in 1976, is now available in paper covers. £5

CENTRALLY ACTING PEPTIDES

Edited by **J. Hughes**

A Biological Council Symposium on Drug Action

The 1977 symposium, on which this book is based, was stimulated by the dramatic increase in research into functionally active peptides in the central nervous system. These peptides are a major group of neurotransmitter agents, and their discovery has given added impetus to brain research. Electrophysiological, biochemical and behavioural techniques have all helped to further our knowledge, with radio-immunoassay and radiofluorescence contributing to major advances in the field.

The papers here deal with all these approaches, and also point out the many gaps remaining in our understanding of peptides. The book thus gives a timely review of the current state of research, and will be invaluable to anyone already involved in the area.

Circle No. 120 on Reader Enquiry Card.

detail (by the factor-label method). Mathematics is treated as a tool and use of calculators is encouraged, especially when working with logarithms (pH). The end-of-chapter problems are grouped into two, roughly parallel sets and the solutions (set-ups shown) for the first set are given in an appendix; the rest of the solutions and suggestions for further problems, demonstrations, audiovisual aids, and so on are provided in an instructor's manual.

New terms are emphasised by italics and marginal notes in a second colour when they first appear; a very thorough index with a key to defined terms makes them easy to find later. Another feature is the appearance of a cartoon character, Maxwell's demon, in the figures. The demon is the author's "alter ego" and allows her to point out important features visually and informally, as many of us would like to do, if we could be present at our students' study. The demon is not gimmick, but an effective pedagogical device to which many students respond very favourably. Newell begins her first edition with the words, "I enjoy chemistry": students and instructors using her text will also.

The difficulties students have in solving problems generally fall into two categories:

interpretation and set-up. The second text is a self-study book that will give little help in interpretation.

The topics covered (in about 1,000 problems with answers) are the usual material of general chemistry: mole concept, stoichiometry, periodicity, atomic and molecular structure, phase properties, equilibria, thermodynamics, solutions, kinetics, and a bit of specific chemistry. (The material has also been used successfully in good high school classes.)

The authors' aim is to provide students with practice in working multiple choice problems to help them bridge the gap between the usual textbook problem statements and those they often meet in examinations. As the format and/or units of the answers are given in multiple choice problems, the student knows what she/he is working toward and is left 'only' the task of combining the information given in an appropriate way to get such a result.

The factor-label method is explained in concise, abstract form in Chapter 1 and then used consistently throughout the worked examples at the beginning of each chapter. Students who have trouble handling algebraic concepts will find the examples difficult to understand. Estimation (order of magnitude

calculation) of numerical results is emphasised as an aid to checking exact calculation and deciding whether a result is 'realistic'; often such an estimate is all that is required to select the correct response.

Occasionally, a bit more detail about the estimation made in the worked example would be welcome. The exact numerical solutions to the examples show what a student will actually see on a calculator followed by a discussion of precision, rounding-off, and significant figures; this approach is a very positive feature of the examples used. Significant figures to be reported in calculated values are explained both in terms of precision of the data and the more rote digit-counting procedure. The distinction between 'measured' and 'defined' values is made clearly in an appendix and applied throughout the text. The problems are straightforward, familiar and dull, that is, they provide no intrinsic stimulus for learning the material. Perhaps this is as it should be; this is a good practise book. The stimulus to practise must be provided by a teacher. □

Jerry A. Bell is Professor of Chemistry at Simmons College, Boston, Massachusetts.

Analytical chemistry

M.S. Greenberg

Analytical Chemistry. Second edition. By Donald J. Pietrzyk and Clyde W. Frank. Pp.700. (Academic: New York and London, 1979.) \$17.50. *Quantitative Analytical Chemistry*. Fourth edition. By James S. Fritz and George H. Schenk. Pp.661. (Allyn and Bacon: Boston, Massachusetts, 1979.) \$19.95.

ANALYTICAL CHEMISTRY by D.J. Pietrzyk and C.W. Frank is a revision of an earlier text and is intended for introductory courses in analytical chemistry, especially those shorter courses servicing chemistry majors and life-science majors. Other texts with this objective dilute the fundamental analytical chemistry to render the text 'relevant' by emphasising analytical applications. By concentrating on fundamental principles of modern chemical analysis and illustrating these principles with applications to chemical, environmental, clinical and pharmaceutical problems, the authors provide the student, with some exceptions, with an excellent introduction to the theory and practice of analytical chemistry.

After a core of six chapters dealing with

prerequisite concepts, the text emphasises five major areas: volumetric methods, potentiometry, spectroscopy, chromatography and electrolysis methods. These chapters are followed by a chapter on experimental techniques and 41 laboratory experiments.

The core chapters include discussions of the nature of analytical chemistry, the analytical method, stoichiometry, statistics, operations in analytical chemistry and chemical reactions. These chapters are well written and very informative about the nature and role of analytical chemistry. However, some important concepts are not pursued in reasonable detail. The statistics chapter introduces the t statistic and confidence limits, but does not demonstrate their use in significance testing. Pronouncing that "the activity concept is an insignificant one" is bothersome. The introductory student should be aware of thermodynamic versus conditional equilibrium constants. Later, the authors note that since ion-selective electrodes respond to ion activity, ionic strength must be held constant to relate potential to concentration. However, the text does not demonstrate the calculation of or relationship between ionic strength and the activity coefficient.

The chapters dealing with volumetric methods of analysis are the best in the text. The authors show the student a chemical approach rather than a formula approach to problem solving — important equilibria are identified, equilibrium constants

written, chemically reasonable, simplifying assumptions are made and the problem solved. Further, the order of the chapters lends clarity to the material. For example, precipitation methods are divided into chapters on gravimetric methods and precipitation titrations, with the latter following the chapter on potentiometry. The chapters on redox methods and ion-selective electrodes are preceded by an excellent chapter discussing conventional cell notation and the Nernst equation. Tables summarising species determined and reagents and conditions for analysis by each method are also presented.

The remaining chapters on instrumental methods of analysis are all descriptive and contemporary. However, the emphasis on fundamentals, so evident in the earlier parts of the text, is missing. Deviations from Beer's law, their sources, elimination and implication in instrument design are not discussed. Instrument components and configuration (single beam, double beam) are not pursued with enthusiasm. On the other hand, differences in configuration for molecular versus atomic absorption instruments are pointed out. Chromatographic methods are developed without discussions of plate and/or rate theory and the Van Deemter equation. Electrolytic methods are introduced but no mention is made of the important new voltammetric methods.

The experiments are those which are done in most courses in analytical

chemistry: analysis of well characterised unknowns. The experiments are presented in a cookbook style, so the instructor may wish to supplement with assigned reading or lectures.

Despite the descriptive nature of the instrumental analysis chapters, this text is one of the best for teaching introductory analytical chemistry. The instructor may wish to supplement the instrumental analysis chapters with more theoretical concepts as noted, but the lucid writing and excellent organisation of this text teach the student to think analytically.

In revising the third edition, the authors of *Quantitative Analytical Chemistry* attempted not only to update the text, but also to make explanations clearer and difficult concepts more understandable. This revision is a significant improvement, and should maintain the popularity of the earlier texts in this series.

The text is intended both for short, introductory courses for chemistry majors and students in related disciplines and for more intensive courses for chemistry majors. The text is arranged in two sections: Part I, Principles and Theory, and Part II, Laboratory Techniques and Procedures. The authors recommend the first 14 chapters for a short course stressing the fundamentals of analytical chemistry, with the more specialised, 11 remaining chapters added for a more modern course in chemical analysis.

As a result of the dual audience objective, the chapter organisation in Part I is not ideal. After some introductory chapters, most texts present discussions of volumetric methods of analysis followed by chapters on instrumental methods. After the expected chapters on the nature of analytical chemistry, the analytical method and statistics, two chapters on gravimetric and spectrophotometric methods are presented. Overview chapters on volumetric methods and chemical equilibria follow immediately, then the theory and applications of aqueous and non-aqueous acid-base, precipitation, complexation and oxidation-reduction methods are presented in seven chapters. The instructor may wish to rearrange the middle chapters, especially moving the spectroscopy chapter to the end. The order of the more advanced chapters on instrumental methods is traditional.

As noted, the revised and new material have significantly improved the text. The statistics chapter is very good, yet a discussion of the use of confidence limits for significance testing would be expected for a majors text. The addition of worked problems in complexation chemistry lends clarity to that discussion. Chapter 5, Spectrophotometric Methods of Analysis, presents an excellent introductory discussion of Beer's law and chemical instrumentation. The best chapters of the text are those dealing with instrumental methods. The reorganised discussion of electroanalytical methods is followed by an

excellent chapter on potentiometry with ion-selective electrodes. As promised in the preface, the chromatography unit is strong, probably the best available in an introductory text. The chapters on atomic and molecular spectroscopy emphasise fundamental principles of spectroscopy and instrumentation, building on concepts presented in Chapter 5.

However, the "new treatment" applied to the presentation of acid-base chemistry was most disappointing. Approximations employed for pH calculations of weak acids and bases are not carefully justified. Although weak acids do ionise to a small degree such that the analytical and equilibrium concentrations of protonated acid will be nearly equal, the assumption is not justified or checked after the calculation. Further, implications of ignoring the autoprotolysis of water are not explored. For diprotic acids, the text states that if $K_{A1} \gg 100 K_{A2}$, the second dissociation may be ignored in pH calculations. Though this approximation is reasonable, it is not carefully justified. While the authors' intention to approach pH calculations by identifying the principal equilibrium and rearranging the

appropriate equilibrium constants is desirable, their presentation is not sufficient. On the other hand, their discussions on feasibility of titrations, indicators and the new chapter on non-aqueous acid-base titrations are good.

Part II is an acceptable laboratory manual. Experiments are grouped into units on analytical operations, gravimetric procedures, volumetric glassware, titrimetric, spectrophotometric, electro-analytical and separation procedures. Each experiment begins with a brief theoretical discussion followed by the procedure and concludes with questions. The experiments are those which characterise most teaching laboratories.

This text, though awkward in chapter progression, will function well in a chemistry majors course in modern chemical analysis. While it would be possible to use this text in a short introductory course, texts written specifically for those courses should be considered also. □

M.S. Greenberg is an Assistant Professor of Chemistry at Kent State University, Ohio.

General chemistry texts

R.O. Ragsdale

General Chemistry/Principles and Structure. Second edition. By James Brady and Gerard Humiston. Pp.786. (Wiley: New York and Chichester, UK, 1978.) \$19.95. *Laboratory Manual for General Chemistry Principles and Structure*. By Jo Beran and James Brady. Pp.520. (Wiley: New York and Chichester, UK, 1978.) \$8.95. *Basic College Chemistry*. By Don Roach and Edmund Leddy Jr. Pp.636. (McGraw-Hill: New York, 1979.) \$16.95.

THE text *General Chemistry, Principles and Structure*, by J.E. Brady and G.E. Humiston is a successful entry in a highly competitive market. Joint efforts between authors and publishers have resulted in a number of excellent texts at the level of Brady and Humiston. Some of them are: *A Conceptual Approach, Chemistry* by C.E. Mortimer (Van Nostrand: New York and London, 1979), *Chemistry, the Central Science* by T.L. Brown and H.E. Le May Jr (Prentice-Hall, Englewood Cliffs, New Jersey, 1977), and *Chemical Principles* by W.L. Masterton and E.J. Slowinski (W.B. Saunders: London and Philadelphia, 1977).

The Brady and Humiston text stands out alone with its unique feature of stereo

illustrations. The stereodiagrams as well as the other illustrations are all well done. I have been successful in seeing all of the stereodiagrams in 3-D. All of the stereodiagrams are not necessary and in many cases students would be better off making their own models.

The text is well organised and well written. It has ample questions and problems. The second chapter, which introduces stoichiometry, has 19 examples and 63 questions and problems at the end of the chapter. The chapter on acid-base equilibria in aqueous solution has 15 examples and 71 questions and problems.

This is a traditional freshman general chemistry text for science and engineering majors. It is intended for both students who have had high school chemistry as well as those who have not. This text is similar to those mentioned above in using a theory and principles approach to the teaching of chemistry. Like the other texts it has a limited amount of descriptive chemistry. It has three chapters on representative metals, nonmetals and metalloids, and transition elements.

The freshman students in the US are probably at the same level as the advanced level students in the UK. The UK students are exposed to much more organic chemistry than their US counterparts. There has been a resistance to texts which offer much more than one chapter of organic chemistry. This is a paradox since many of these students will not be taking any more chemistry. This resistance to organic is also true for descriptive chemistry.

The Brady and Humiston text is very readable and the second edition seems to be an improvement over the successful first edition. Textbook authors are slowly going to the SI units. This text makes use of both SI units and the metric system. It will probably be some time before there is complete conversion to the SI system.

Most successful US books now come with a complete teaching package and Brady and Humiston is no exception. There is a student study guide available as well as a laboratory manual. The book, *Laboratory Manual for General Chemistry Principles and Structure* by J.A. Beran and J.E. Brady, has been designed to accompany the textbook. This manual is also suitable for a number of general chemistry texts.

The laboratory manual contains both quantitative and qualitative experiments (altogether 44 experiments). The emphasis on organic chemistry in the US general chemistry is reflected in the laboratory manual as 2 out of 44 experiments involve organic chemistry. There is a lack of emphasis on accuracy and precision in measurement in the manual.

In the first part of the manual 18 laboratory techniques are illustrated by actual photographs whose reproduction in the text are of high quality. For beginning students these instructions will be invaluable. The authors do have an

annoying habit of continually referring to these techniques. One would hope that the students would be able to refer back to the techniques themselves instead of the cookbook instructions (. . . "remove copper from the rubber policeman . . . (Technique 6)" and " . . . heat the copper metal to dryness with a Bunsen burner (Technique 9(a))". The experiments all have a report sheet with questions and a pre-laboratory assignment sheet with questions and problems.

There are some interesting experiments. The law of multiple proportions is demonstrated by starting with copper (II) bromide and converting it to copper (I) bromide. Copper is obtained by displacement with magnesium. A limiting reactant experiment is achieved by taking an unknown mixture of the salts $\text{Na}_3\text{PO}_4 \cdot 12\text{H}_2\text{O}$ and $\text{BaCl}_2 \cdot 2\text{H}_2\text{O}$ and adding water to them. Barium phosphate precipitates and one determines the limiting reactant and the composition of the salt mixture.

The third book that I reviewed left me in a quandary as to the students for whom it was intended. The text, *Basic Chemistry* by D. Roach and E. Leddy Jr, has a table of contents which is similar to texts that are used for science major courses. The authors give no indication in the preface for whom it was written. After perusal of the text, I came to the conclusion that it was

written for nurses and students in the allied health fields as the text is definitely a full level below Brady and Humiston. Some texts which are similar in level are *Foundations of College Chemistry* by Hein (Dickenson: Encino, California, 1977), *Basic College Chemistry* by Mitchell (Harper and Row: New York, 1978) and *Introduction to Chemistry* by Dickson (Wiley: New York and Chichester, UK, 1979). Roach and Leddy's text is longer than the ones mentioned above by some 100 pages. Many nurses' courses do general chemistry for one semester and in some cases only one quarter. The rest of the year is spent on organic and biochemistry. If the book is intended for this audience it has perhaps missed the mark.

It is conceivable that junior college and community college students might spend a year on a low level course. If these students then decided to go along the science major route they would need to take a Brady and Humiston type course.

Roach and Leddy's book uses a definition approach to chemistry. This approach makes the text seem quite sterile. The more difficult problems are starred. One wonders when a problem such as '4.21 g/ml = ? g/liter' is starred. □

Soil chemistry

P.H. Nye

Soil Chemistry. A. Basic Elements. Edited by G.H. Bolt and M.H.M. Bruggenwert. Pp.281. (Elsevier: Amsterdam, Oxford and New York, 1978.) \$19.95. *B. Physico-Chemical Models.* Edited by G.H. Bolt. Pp.479. (Elsevier: Amsterdam, Oxford and New York, 1979.) \$73.25.

THESE two volumes have been largely written by Professor Bolt and his colleagues at the Agricultural University of Wageningen, The Netherlands. Part A (*Basic Elements*) is intended as a textbook for advanced undergraduates. Part B (*Physico-Chemical Models*) elaborates the theoretical material of Part A. Both parts concentrate on physicochemical aspects, and a general title such as "Soil Physical Chemistry" would have been more appropriate than *Soil Chemistry*.

The strength of Part A lies in its sound theoretical development, its sensible ordering of topics, its uniform symbolism and terminology in spite of nine authors, and the numerical examples at the ends of the chapters. There is no other textbook

covering the same ground at an advanced level.

The first chapter on the composition of the soil, and the second, a potted account of chemical, especially solubility, equilibria summarise the background anyone who hopes to understand the book must have. A fairly intelligible account of double layer theory and cation adsorption and exchange follows. The chapter on solubility equilibria in soils, including redox reactions involving iron, which are treated in terms of electron activity pe , is good. Chapter 7, "Transport and Accumulation of Soluble Soil Components", is often obscure (figure 7.1, for example, and the phrase "autonomous flux of solute"), though the distinction between self-sharpening and diffuse boundaries in solute displacement is well presented. These theoretical treatments are then used by Van Beeman and Brinkman to discuss soil formation in a way that achieves the right balance between ideal equilibrium and real non-equilibrium behaviour. The application of theory to saline and sodic soils is well presented. The volume concludes with an interesting account of soil pollution, which contains much more descriptive material than elsewhere in the book. We learn, for instance, that 60–90% of the deaths of street trees in Dutch town centres are caused by gas leaks following conversion to

natural gas. This section should convince students that the theory they have been invited to master in previous chapters is essential to understanding the fate of the great variety of pollutants now being dumped on the soil.

This second edition has eliminated many of the errors and 'Dutchisms' that occurred in the first edition. Unfortunately, the term "Free Enthalpy" is perversely retained throughout for Gibbs free energy G , without explanation. The uncertain student, having learnt to make this mental switch, will be mystified to read on p.14 that "to each chemical species in a reaction mixture a certain amount of ('free') energy can be ascribed." The phraseology is often awkward and some curiosities remain, such as a "gift" of irrigation water. It is a pity that the opportunity was not taken to have the text revised by an English writer.

Part B is considerably more difficult than Part A. The first half attempts to explain the relation between the proportions of exchangeable cations adsorbed on negatively charged clay and soil surfaces and their proportions in an equilibrium solution. Chapters 1, 2 and 3 by Bolt develop from first principles the theory of the diffuse double layer, the thermodynamics of cation exchange and the distribution of cations of differing charge in the electric field created by uniformly charged negative surfaces.

Much of this is Professor Bolt's own contribution to the subject, and it is good to have it collected together. The theory developed has limited application because it assumes the surface charge is uniform. In reality, the negative charges are discrete, so it is gratifying that Chapter 4 by Harmsen deals specifically with discrete site models, leading to a full account of the application of Guggenheim's theory of mixing to cation exchange equations. Diffuse double layer theory does not enable one to decide whether the selectivity coefficient in a heterovalent exchange (for example, $K^+ - Ca^{2+}$) is more likely to be constant if the activity of an adsorbed cation is represented by its equivalent fraction (Gaines and Thomas equation) or its mole fraction (Vanselow equation). The conclusion reached from mixing theory is that the selectivity coefficient should always lie between these two extremes. Up to this point Chapter 4 is well worth the effort; it then gets lost in remote realms of speculation, assuming various arrangements of discrete sites.

We are brought back to earth in Chapter 5. Bruggenwert and Kamphorst tabulate in uniform fashion thermodynamic data on 350 cation exchange reactions on clays, 265 on soils and a further 119 for heavy metals on soils, the last providing useful evidence of the high affinity of soil for these elements at low surface coverage; otherwise, they are able to draw disappointingly few conclusions from their mammoth collection of data.

In Chapter 6, Maes and Cremers consider the effect of surface charge density on ion selectivity in clays. In the exchange between mono- and divalent

ions, they show that a simple electrostatic model is only partially successful because of ion-solvent interactions that are difficult to calculate. The corresponding discussion of exchange between homovalent ions (sections 6.1.3 and 6.1.4) is marred by obscure and slipshod writing, and the accompanying tables (numbers 6.3 and 6.4) omit to mention the ions for which data are given. The greatly increased stability of ion complexes, such as copper-ethylenediamine, when adsorbed on clay surfaces is clearly described.

In a valuable account of anion exclusion from negatively charged surfaces, Bolt and de Haan suggest that the apparent reduction of chloride exclusion from the surface of calcium montmorillonite is caused by plate condensation rather than ion pair formation as suggested by Edwards, Posner and Quirk. This controversy badly needs settling by further experimental work.

A highly compressed chapter on the interaction of orthophosphate ions with soil lacks critical insight into the complex reactions described. If adsorbed anions were not to be more comprehensively covered — and phosphate is the only anion considered — this chapter might have been omitted.

The last third of the book deals with kinetics. Bolt treats movement of electrolytes in artificially packed soil columns in terms of advanced chromatography theory, and the few who will stay the course will be rewarded by a "guideline for guessing" the development of displacement fronts at the end of the chapter. Van Genuchten and Clearey extend this treatment to undisturbed

profiles, and show lucidly that a model based on zones of mobile and immobile water has marked success. Bolt and Groonevelt's chapter (Chapter 11) on electrokinetic phenomena in soil is the best account I have read and is neatly unified in terms of the thermodynamics of irreversible processes. The concluding section on the conductivity of clay suspensions reveals that exchangeable ions on clays have considerable surface mobility (p. 422), yet the treatment of diffusion effects in soil columns (p. 299) implicitly assumes that exchangeable ions are immobile. This inconsistency is not discussed. In fact, exchangeable ions in soils do have very different mobilities from exchangeable ions in clays, and the reasons for this important difference should have been referred to.

The book concludes with a suggestive account by Brinkman of clay transformations, in which the equilibrium and kinetic ideas developed in earlier chapters are applied to the long-term processes of soil formation. An advanced text on soil development from this viewpoint is badly needed and since good field men with an equally good understanding of physical chemistry are rare, perhaps Brinkman could be encouraged to write it.

This book should certainly be acquired by soil science libraries, and by wealthy workers in the fields of ion exchange and solute movement in porous media. □

How to know

Almut G. Jones

How to Know the Grasses. Third edition. By Richard W. Pohl. Pp.200. (Brown: Dubuque, Iowa, 1978.) Clothbound \$8.95; paperbound \$6.95. *How to Know the Mosses and Liverworts.* Second edition. By Henry S. Conard and Paul L. Redfearn Jr. Pp.302. (Brown: Dubuque, Iowa, 1979.) Clothbound \$8.95; paperbound \$6.95. *How to Know the Lichens.* Second edition. By Mason E. Hale. Pp.246. (Brown: Dubuque, Iowa, 1979.) Clothbound \$8.95; paperbound \$6.95. *How To Know the Seed Plants.* By Arthur Cronquist. Pp.153. (Brown: Dubuque, Iowa, 1979.) Clothbound \$8.95; paperbound \$6.95. *How to Know the Ferns and Fern Allies.* By John T. Mickel. Pp.229. (Brown: Dubuque, Iowa, 1979.) Clothbound \$8.95; paperbound \$6.95.

THE five volumes of the popular, economically priced, *How to Know* series reviewed here have certain features of format and organisation in common upon which I wish to comment beforehand. They are intended to serve the amateur naturalist and the serious student, as well as the professional scientist. In contrast to the pocketbook format of earlier editions (preferred by me for the books intended as field guides), they are of notebook size (19×23 cm). The paperback versions have a spiral-coil back, and a rather frangible cardboard cover not very suitable for the rigours of fieldwork. Following the instructive introductory chapters, the body of each book is comprised of abundantly illustrated keys. The final pages are assigned to a combined index and, usually pictured, glossary. In my opinion, ease of finding would be enhanced if these last two items were separated.

As the two earlier versions of *How to Know the Grasses* were authored by the same renowned agrostologist (R. W. Pohl), the reader would expect an expertly written

and polished product in this third edition. He will not be disappointed. The booklet includes keys, illustrations and distribution maps for 324 of the most common grasses of the US. Most of the meticulous drawings were done by the author himself. Following the system of classification published by Stebbins and Crampton in 1961, six subfamilies are recognised. Chapters of the introduction are devoted to definitions of structural terms. A key is provided distinguishing grasses from sedges and rushes. The student is instructed on how to collect and prepare scientific specimens. A list of 29 references suggests supplementary literature. Preceding the artificial keys to genera and species is a chapter on recognising the grass tribes and a preliminary key to major groups. Although clearly written for the beginner, the book will also appeal to the seasoned naturalist and the professional plant systematist. It is an excellent field and laboratory guide and a must for any student of grasses.

Billed as the second, this is actually the

third edition of this handy guide to the North American mosses and liverworts, *How to Know the Mosses and Liverworts* (by H.S. Conard and P.L. Redfearn Jr). While the amateur will be overwhelmed with the variety of forms and hidden structural beauty of these unobtrusive flowerless plants, the professional botanist will be impressed with the careful detail shown in the illustrations, as well as the endeavour for scientific accuracy apparent in the organisation of the contents. Introductory chapters deal with life cycles, diagnostic characteristics, habitats, preparation of specimens, and classification of categories above the level of family. Approximately 1,700 species of bryophytes occur in North America, and all the common ones can be identified using this booklet. Since the previous edition, 112 species and 42 genera have been added. The strictly dichotomous keys are broken up so that the user first arrives at the generic name and then finds the species under each genus. A brief descriptive paragraph is provided for each species. As recent taxonomic revisions have resulted in a considerable number of name changes, a list of synonyms is included. A bibliography of 35 entries inspires background and supplementary reading. The book is a treasure as a field guide, and it is definitely orientated to be a text in an introductory bryology course.

How to Know the Lichens by M.E. Hale is an attractive field and laboratory guide to the identification of lichens. It is a revised and an enlarged version of the first edition prepared, after an interval of 10 years, by the same author. There is little difference between the two editions in general outline and organisation. The geographical region considered is the North American continent but, as many lichens have a circumboreal distribution, the keys are largely applicable to the lichen flora of the entire Northern Hemisphere. Seventy new entries have been added since the first edition, bringing the total to 427. Only foliose, fruticose and squamulose lichens are treated, the crustose forms having been omitted "because they are too numerous and too little known". In the introduction, the student is informed about the symbiotic nature of lichens, about their economic uses and their sensitivity to air pollution. Several well illustrated pages are devoted to chemical, colour and crystal tests which are so essential for the identification of lichens. The student is further instructed in the use of technical terminology and in methods for storage and culture of specimens. A list of 37 references gives sources for additional information. All keys are dichotomous and conveniently broken up. Keys for the main sections are preceded by alphabetic lists of genera with a citation of their salient features. In addition to descriptions and illustrations for the major species, inset maps indicate their ranges of distribution. The keys are followed by a list

of synonyms and a classification of genera and species. The booklet constitutes an authoritative text well suited for any course on lichen systematics.

How to Know the Seed Plants by Arthur Cronquist, is a successor to the section on seed plants in H.E. Jaques' *Plant Families: How to Know Them* (1949). Approximately 375 families of seed plants are recognised and those represented by plants growing spontaneously or frequently cultivated in the US are treated in the dichotomous keys. Each family is identified by both vernacular and scientific names. In addition to a description, each entry gives information on common genera and on geographical distribution. One or more of the characteristic species are illustrated. Whereas I consider the booklet a worthwhile addition to my botanical library, I doubt whether the uninitiated amateur, who is so obviously addressed in the rather perfunctory introduction, will find it all that attractive. Amateurs have generic concepts; they may think, for example, in terms of cottonwood, lilac, clover, carnation, and so on, but would not ordinarily view these plants as members of Salicaceae, Oleaceae, Fabaceae, and so on. The book is not, nor intended to be, a substitute for an amateur's field guide. In my opinion, the introduction is aimed at too low a level of scholarship, and falls short of giving adequate background and technical instruction to potential readers who really would appreciate a text with pictured keys to the families of seed plants, namely college students and their instructors, as well as reasonably well informed naturalists. The brief chapter on principles of classification and nomenclature does not do justice to either the excellent keys or the phylogenetic outline of classification. The omission of a bibliography on background and supplementary literature is hardly forgivable and definitely impairs suitability

of the book for college-level courses on plant identification and systematics.

It is an inspiration to leaf through a scholarly prepared text like *How to Know the Ferns and Fern Allies*, by John T. Mickel. The volume succeeds in fulfilling the need for a modern field guide to all the North American petridophytes. To accommodate the amateur, technical terminology has been minimised, but without sacrificing clarity and accuracy. As emphasis rests on identification, family names are avoided and, within the major groups, the plants are keyed directly to the generic names. Species are treated in secondary keys under the alphabetically arranged genera. Identification is aided by diagnostic drawings, as well as inset maps indicating geographical distribution. Relationships among North American fern genera are presented diagrammatically at the beginning of the text. Several chapters preceding the keys furnish a comprehensive introduction to definitions of structural characteristics, life cycles, hybridisation and cytological phenomena, techniques for spore culture, as well as instruction on how to establish a fern garden and how to prepare herbarium specimens. Valuable bibliographical references are given not only at the end of some chapters, but also in the form of a list of 54 state and regional identification manuals. Preceding the index and glossary is a checklist of North American ferns and fern allies. The book is highly recommendable as a text in college courses at any level; it will also be regarded as a valuable reference work by naturalists and professional scientists dealing with the vascular cryptogams. □

Almut G. Jones is Curator of the Herbarium and Assistant Professor of Botany in the Department of Botany, University of Illinois at Urbana-Champaign, Urbana, Illinois.

Introduction to phycology

M. G. Kelly

Introductory Phycology. By F. R. Trainor. Pp.525. (Wiley: New York and Chichester, UK, 1978.) \$21.50. *Biology of Seaweeds/Levels of Organization*. By A. R. O. Chapman. Pp.134. (University Park Press: Baltimore, 1979.) \$10.75. *Introduction to the Algae: Structure and Function*. By Harold Bold and Michael Wynne. Pp.706. (Prentice-Hall: Englewood Cliffs, New Jersey, 1978.) \$36.40.

ALGAE are responsible for most of the energy input to marine and freshwater communities. They play a major role in controlling water chemistry, especially of oxygen, pH and nutrients. The types of algae in a water body often determine the species composition of the higher trophic levels. Algal productivity controls the locations of the world's major oceanic fisheries. In lakes, too few algae mean a poor fishery sport while too many mean extreme water quality problems. It can be easily argued that algae are fully as important as the land plants.

As Trainor points out in *Introductory Phycology*, these factors have led to an increased interest in algae, not only on the part of biologists, but also by water quality

A bioluminescent marine dinoflagellate

From *Biology* by Helena Curtis, reviewed on page 106

engineers, geochemists and others. This increased interest has produced a need for modern texts on phycology: these three respond to that need.

The shortest of these books, *Biology of Seaweeds/Levels of Organization* by Chapman, is the most specialised. Although it deals only with the macroscopic algae of coastal areas, it provides much basic information for a general algology course. The other two texts are comprehensive, in that they cover all of the phylogenetic groups. They are also 'classical' in approach, proceeding group by group, emphasising the taxonomy, morphology, reproduction, and to a much lesser degree physiology, biochemistry, ecology and distribution. Chapman, on the other hand, proceeds on the basis of levels of organisation, progressing from cellular ultrastructure through the ecology of communities. I find Chapman's approach much more appealing. It provides a holistic understanding of 'how algae work', that is, how they are adapted to exist and function within an environment. The book emphasises ideas and leads a student's train of thought within an organised framework. The approach of the other two books leads to rote memorisation and a fragmentation of ideas which students (and thoughtful professors) may find less than appealing. On the other hand, the book by Trainor and *Introduction to the Algae: Structure and Function* by Bold and Wynne are organised in the way many algology courses are taught, and this alone will probably increase their acceptance.

All three texts differ in the way algae are divided into divisions and classes. Trainor uses five divisions, and Bold and Wynne use nine. Chapman discusses three (those containing marine macroalgae), and simply avoids mentioning the controversies of classification by usually referring simply to red, brown and green algae. His approach seems most sensible. Why teach a scheme of classification and set of terminology that authorities disagree upon and that will probably be completely revised in a few years? Bold and Wynne and also Trainor recognise this problem. The former state "... nature mocks human categories' and this certainly seems

to be the case when one compares the more or less current systems of classification ...". Trainor quotes Dodge as stating that classes "... are the only stable feature which has persisted through the numerous classification schemes of the past few years". Perhaps both books should have followed Dodge's suggestion — don't confuse students by using conflicting classification schemes at the division level.

The two classically organised texts, Trainor, and Bold and Wynne, are very different in the amount of detail presented. Trainor is sparsely referenced and reads like transcripts from a set of very lucid lectures. Wynne and Bold, on the other hand, include 87 pages of references and the text, in places, reads like a monograph. Both provide generic examples, but Trainor's are often very sketchy while Bold and Wynne's are usually too detailed for teaching use. The difference is illustrated by the discussion of the genus *Hormotilopsis*, a somewhat obscure green soil alga first described by both Trainor and Bold. Both texts refer to it. Trainor uses it as an example of dispersion of unicells derived from planospores, but says nothing else about it so that it remains an unassociated Latin name in a student's mind. Bold and Wynne, on the other hand, feel they must tell the student that it is distinguished from *Hormotila* by having quadriflagellate rather than biflagellate zoospores, provide several illustrations, and tell when and by whom it was first isolated. I think most algologists would agree that a student would not be deprived if he never heard of either genus.

Chapman's book, published by a fairly small firm, contains few, if any errors in composition and editing. The other two, published by major houses, contain major errors. For example, in Bold and Wynne a block of text is missing on page 5. In Trainor figures 17-6 and 17-7 are identical. The caption for one states it shows algae washed ashore after a storm, while the other is supposed to be the intertidal of the Arctic; reproduction of the illustrations was so poor I was unable to tell which, if either, was shown.

A major reason for the increase of interest in algae is recognition of the importance of their ecology. Bold and Wynne deliberately avoid this topic, Trainor includes material, but much of it is solely descriptive and out of date, and nearly all would be covered in an introductory ecology course. Chapman, within his limited scope, provides an outstanding and stimulating discussion.

In summary, I will recommend Trainor to a student who wants to read about algae without taking a formal course. Bold and Wynne will become a well worn member of my reference shelf and will be owned by all of my graduate students. Finally, I look forward to someone writing a text with the organisation, style and balance of coverage that Chapman has but which covers all of the important groups. □

M. G. Kelly is Associate Professor at the Department of Environmental Sciences, University of Virginia, Charlottesville, Virginia.

Entomologically speaking

R.W. Thorp

How to Know the Insects. Third edition. By Roger Bland and H.E. Jaques. Pp.409. (Brown: Dubuque, Iowa, 1978.) \$7.95. *How to Know the True Bugs*. By J.A. Slater and R.M. Baranowski. Pp.256. (Brown: Dubuque, Iowa, 1978.) \$6.95. *How to Know the Spiders*. Third edition. By B.J. Kaston. Pp.272. (Brown: Dubuque, Iowa, 1978.) \$6.95. *How to Know the Mites and Ticks*. By Burruss McDaniel. Pp.335. (Brown: Dubuque, Iowa, 1979.) \$7.95.

Two new volumes and two revised third editions dealing with insects and arachnids have been published in the *How to Know* series since 1978. All four have a plate size 2×4.5 cm larger than earlier editions with an easier to read double column format. One problem with the volumes on true bugs, spiders, and especially mites and

ticks is that descriptions of genera, species and keys to species are inserted among the couplets of the keys to genera, occasionally separating halves of these couplets by up to two pages. Since many of the taxa treated in these volumes are cosmopolitan, they may prove useful as identification manuals in other countries.

In most particulars, the edition of *How to Know the Insects* by R.G. Bland and H.E. Jaques is a vast improvement over the second edition: more than half again as many families are keyed; families of scale insects (Coccoidea) are not keyed, but are discussed and diagnosed; family discussions include more complete descriptive and biological data; many subfamilies of large families of Orthoptera (Acrididae, Tetigoniidae, Gryllidae), Coleoptera (Scarabaeidae, Chrysomelidae, Cerambycidae, Curculionidae), Lepidoptera (Saturniidae, Arctiidae, Pyralidae) and Hymenoptera (Formicidae, Vespidae, Sphecidae) are diagnosed and discussed, although keys are not provided; there are many more illustrations and their larger size, improved quality and detail make them much more useful; the classifications are more current and orders and

families are organised in a more closely phylogenetic sequence; although illustrations are not included in the terminal Index and Glossary, references to appropriate text figures are found with each term defined. Missing are the useful systematic lists of families of North American insects for each order. Also gone are the folksy humour and enthusiasm of the initiator of the series, Professor Jaques, but these are replaced by more precise and erudite discussions of the diversity and interest of insects.

Introductory chapters on how to collect, preserve, mount, curate, observe, rear and where to look for insects are concise and well done. The chapter on structure and development is brief, but does seem to cover the bare essentials of structure necessary to use the keys. The keys are well constructed, with a minimum of technical jargon allowing easy use even by a novice. A key to orders of adult insects is followed by treatments of each order.

Each order is introduced with a brief descriptive diagnosis, habits, life histories, habitats occupied, special collecting and curating techniques, and estimates of the numbers of species and families in North America and species worldwide. This is followed by a key to the common families of the order. The family key is followed by brief structural diagnoses of each family, their principal habitats and often by brief descriptions of the most common species. A list of general references usually concludes each ordinal treatment.

Few errors of any import were noted. The reference to one of the best new textbooks on entomology by H.V. Daly, J.T. Doyen and P.R. Ehrlich, *An Introduction to Insect Biology and Diversity* (McGraw-Hill: New York, 1978), is curiously included within the reference to the book by M.D. Atkins. Missing from the same list of general references in insect biology is another important multi-authored book edited by D.F. Waterhouse (*The Insects of Australia*. Sponsored by CSIRO, Canberra. Melbourne University Press, 1970). Although the key to Mecoptera families correctly states that Bittacidae have only a single large claw on each tarsus, figure 223A clearly shows two tarsal claws on each leg of *Bittacus apicalis* Hagen.

The quality of the illustrations in this volume is not on a par with those in the better known field guides. However, it does provide keys for identification which the field guides usually do not and the keys are simpler and easier to use than those of the more expensive general texts. Although this volume lacks lists of family group and higher classificatory taxa for each order, its coverage of over 60% of the families of America north of Mexico, its clear, concise, accurate keys and descriptions, and its relatively low price make it an attractive alternative to the texts for field and laboratory courses devoted to identification and classification of adult insects.

How to Know the True Bugs by J.A. Slater and R.M. Baranowski is an excellent addition to the series, and includes keys to the families of Hemiptera-Heteroptera of North America, to 475 genera, and to 65 species and 2 subspecies in 10 of these genera. In addition to the usual introductory material on life history and morphology, and collecting, preserving and labelling methods, a special historical section introducing early European and American hemipterists is included. Following the key to families based on adult Hemiptera is a separate key to families based on nymphs. The majority of the book consists of family treatments introduced by brief descriptions and biological information, most followed by a key to genera with brief discussions of each genus often followed by descriptions of common species. Most of the family treatments end with references to pertinent literature. At the end of the book is a list of common names of true bugs as approved by the Entomological Society of America, followed by the standard index and glossary.

Few errors of any import were found. In the key to genera of Coreidae the genus *Thasus* was apparently omitted from the first half of couplet 2. The illustrations are of excellent quality. The keys are clear, concise and easy to use. This volume will be useful to all who have occasion to identify the genera true bugs. I know of no other single reference which serves this need for all of North America.

The larger format of the new edition of *How to Know the Spiders* by B.J. Kaston has increased the size of the illustrations and improved their clarity, quality and usefulness, especially those showing webs and snares. More than 40 new figures have been added, and the cartoons of the second edition have been deleted. A new chapter presenting a pictured key to the orders of Arachnida increases the utility of this volume, and places spiders in the context of their closest relatives. One of the more useful features of the second edition which has been carried forward into the current edition is the list of families of spiders arranged in their higher classification groupings and with footnotes denoting families which have representatives in America north of Mexico. The bulk of the book is devoted to descriptions of the families and keys to the more common genera. The additional genera and species treated in this volume bring the coverage to nearly double that of the original volume. Since nine families are uncommonly collected, they are only briefly discussed at the point where they come out in the key to families and therefore do not appear in the list of families in the table of contents.

The volume could be tightened up a bit by eliminating repetition of several figures, some of which are reprinted on four separate pages (for example, *Atypus niger* ventral view is used for Figs 26, 49, 63, 160), where a single figure with subsequent

references to it would suffice. Nonetheless, this volume remains the best resource for identification of North American spiders.

McDaniel should be complimented on his attempt to produce in *How to Know the Mites and Ticks* an identification manual for such a taxonomically difficult group. Especially creditable is the key to families and genera of the Oribatei. Most of the figures are well done and useful. However, figures 1-3 in the section on morphology could stand enlargement and the captions are missing for some (for example, 12, 13, 18, 25, 99-102, 113) or separated by a column or even a page from the figure they belong to. Hypopi of astigmatid families (for example, Acaridae, Anonitidae and Glycyphagidae) are figured and some are diagnosed.

This volume would benefit from the inclusion of a list giving the higher classification (order to families) rather than referring the reader to the excellent manual by G.W. Krantz (*A Manual of Acarology*, 2nd edition, OSU Book Stores: Corvallis, Oregon, 1978). This volume suffers from uneven treatment of taxa with considerable space devoted to such families as Pyemotidae, Chyletidae and Listrophoridae while economically and medically important large families such as Eriophyidae, Tetranychidae and Trombiculidae have only one species treated. The so-called keys to genera of many families are not dichotomous keys with contrasting couplets, but rather a sequential series of generic diagnoses (for example, Spinturnicidae, Tarsonemidae, Pyemotidae, Chyletidae, Tenuiplapidae, Stigmaeidae, Tydeidae, Saproglyphidae, Psoroptidae, Glycyphagidae, Anonitidae, Pyroglyphidae, Listrophoridae, Sarcopidae, Epidermoptidae, Chirodiscidae, Myocoptidae). The key to species of *Ornithodoros* should be set in a smaller typeface with different couple designations so as to distinguish it from the surrounding key to genera of Metastigmata (compare keys to species of *Ornithonyssus* and *Psoroptes*).

Although this volume is unlikely to replace or even supplement the more expensive manual by Krantz in laboratory courses in acarology, it will prove a valuable tool for less specialised courses dealing with terrestrial arthropods, and for state and federal workers and other researchers who have occasion to make preliminary sorts of mites to be sent to specialists for determination. □

A tiger beetle

Animal behaviour

J.P. Hailman

The Ecology and Evolution of Animal Behavior. Second edition. By Robert A. Wallace. Pp.284. (Goodyear: Santa Monica, California, 1979.) Price please. *Animal Behavior: An Evolutionary Approach*. Second edition. By John Alcock. Pp.532. (Sinauer Associates: Sunderland, Massachusetts, 1979.) \$16.00 cloth. *Evolution of Behaviour*. By Jerram L. Brown. Pp.760. (W.W. Norton: New York, 1975.) \$17.95. *Insect Behaviour*. By Robert W. Matthews and Janice R. Matthews. Pp.507. (John Wiley: New York and Chichester, UK, 1978.) \$32.40. *Comparative Animal Behaviour*. By Donald A. Dewsbury. Pp.452. (McGraw-Hill: New York and London, 1978.) \$17.95.

THE closing year of the decade added at least three textbooks on the increasingly popular study of animal behaviour. Robert A. Wallace's *Ecology and Evolution of Animal Behavior* appears in a second edition, with 16 chapters embracing such topics as "classical instinct theory", drive, learning, communication, sex, aggression and social behaviour including altruism and warfare. The frontispiece is clearly a discus (*Symphysodon*), and on page 118 where the figure is repeated we learn that it illustrates "false eyespots near their tail."

The figure might be symptomatic of a second major problem of this book: the common discus species known to aquarium buffs (*S. aequifasciata* and *S. discus*) have no such eyespots, I cannot find such a marking in illustrations of *Symphysodon* species, and an ichthyologically knowledgeable colleague knows of no such species. It would have been useful for the book to identify all species illustrated. Surely the "peregrine falcon" in figure 2.2 is peculiar for the species, and in any case is landing rather than hunting as asserted. Sea horses (figure 2.5) suck up prey somewhat like a vacuum cleaner does, rather than snapping them as asserted. Although some instructors may like the chatty, anecdotal nature of the text, I find it slightly condescending and certainly no paragon for undergraduate writing.

John Alcock's widely used *Animal Behavior: An Evolutionary Approach* appears in a second edition that shows some, but not marked, improvement over the first. This is not a general text on behaviour, but rather is aimed at ecological and evolutionary aspects. There is some material on immediate control of behaviour and its physiological mechanisms, but the author deals only briefly with learning and ontogenetic

development. Indeed, the brief treatment of ontogeny is totally puzzling, as evidenced by such sentences as: "Please note that I am NOT arguing that innate behavior patterns are genetic or more genetic than learned behaviors." When Alcock is in his evolutionary element, however, the text is extremely good, and I believe that a perceptive instructor could utilise it in conjunction with other material.

Because of the similarity with Alcock's book, Jerram L. Brown's *Evolution of Behavior* deserves at least passing mention. The focus is the same, but there is more material on both physiological mechanisms and ontogenetic development of behaviour, making the book more comprehensive, if a few years older. Like Alcock and most other evolutionary behaviourists, Brown finds environmental influences on the development of behaviour slightly annoying, but at least he faces the annoyance reasonably honestly rather than trying to explain it away with semantics.

For entomological ethologists the new *Insect Behavior* by Robert W. and Janice R. Matthews is the first real text of its kind. Although I claim no expertise in insect behaviour, I found the organisation of this book well suited to its subject matter, and those subjects that I know something about to be treated well. Finally, one need mention Donald A. Dewsbury's *Comparative Animal Behavior*, a book (by

a psychologist) with too much elementary zoological material but with a marvellous balance of treatment among the four classes of behavioural determinants — control, ontogeny, perpetuation and phylogeny of behaviour. The text is not, however, orientated substantially toward natural history and field studies, so has not earned plaudits from my students to match my own.

It is difficult to escape the conclusion that a really outstanding text on animal behaviour has yet to be written for a modern audience. Many teachers still rely on one of the three originals, two in revised editions: *Mechanisms of Animal Behavior* by Peter Marler and William J. Hamilton III (Wiley: New York and Chichester, UK, 1966), *An Introduction to Animal Behavior: Ethology's First Century* by Peter H. Klopfer (Prentice-Hall: Englewood Cliffs, New Jersey, 1974) or *Animal Behaviour: A Synthesis of Ethology and Comparative Psychology* by Robert A. Hinde (McGraw-Hill: New York, 1970). Each has its own strengths and weaknesses and all have been well reviewed over the years. A cynic might prefer to follow the dictum of Louis Agassiz: "Learn from nature, not books."

Introductory chemistry for the health sciences

A.D. Cooper

Chemical Principles for Life. By Lois Forney. Pp.574. (Prentice-Hall: Englewood Cliffs, New Jersey, 1978.) \$14.95. *Elements of General and Biological Chemistry*. Fifth edition. By John Holum. Pp.571. (Wiley: New York, 1979.) \$16.95. *Chemical Principles for the Life Sciences*. Second edition. By Ralph Fessenden and Joan Fessenden. Pp.526. (Allyn and Bacon: Boston, 1979.) \$18.95.

ALL three texts are well written. Forney writes at a higher level than the other authors. Particularly difficult concepts covered by Forney are: thermodynamics, Henderson-Hasselbach equation, coupled reactions, standard reduction potentials and titration curves. Difficult concepts are often covered relatively early in the text.

Holum writes at a lower level than the others. Fessenden and Fessenden write at an intermediate level that can be understood by most students. The authors are patient and approach each topic in a systematic way. Difficult concepts covered by the Fessendens are equilibrium constants and coupled reactions. In general, Forney and the Fessendens define terms more clearly than does Holum.

Of the three texts, Holum's has the most special features. Each chapter has a summary, selected readings and ample questions. Worked out examples are included and answers to in-chapter exercises are at the back of the book. Appendices include mathematical manipulations, inorganic and organic nomenclature, and data on nutrition. At the end of each chapter the Forney text has a programmed review that includes fill-in-the-blank questions with answers in the left-hand margin. Some of the chapters have additional questions and mathematical problems. Worked out examples are included. No appendices are given. The Fessenden text has a set of objectives at the start of each chapter and study questions at the end. Numerous well

worked out examples are included. The appendix on mathematical manipulations is thorough. Answers to odd-numbered study questions are at the back of the book.

The Holum text is well illustrated, with many pictures and coloured plates. However, the illustrations in the Forney and Fessenden texts are more than adequate. The figures of Forney's text are in black with shades of grey. Those of the Fessenden and Holum texts are in shades of blue and grey with section headings in blue. The Holum text contains 22 chapters whereas the Forney and Fessenden texts contain 31 and 30 chapters, respectively. The order of chapters and topics are similar with few exceptions. Nuclear chemistry and radioactivity are treated in Chapter 5 by Forney, in Chapter 10 by the Fessendens and in Chapter 22 by Holum. The treatment of electrolytes, body fluids and acid-base balance is presented in the general chemistry unit by Forney whereas these topics are treated in the biochemistry unit by the Fessendens and Holum. The Fessendens have separate chapters on oxidation-reduction reactions, introducing organic chemistry, introducing biochemistry, molecules in three dimensions (optical isomerism), and a chapter entitled Minerals, Vitamins and Drugs. In contrast, Holum and Forney have only the chapter on introducing organic chemistry.

All three texts give a good treatment of the principles of general chemistry, with Fessenden and Fessenden giving the most careful and straightforward presentation. An integral part of many introductory chemistry courses is mathematical problem solving. The Forney and Holum texts give a modest number of mathematical problems. The Fessenden text gives a much more quantitative treatment than the others. Of the three, the Holum text gives the most abbreviated treatment of organic chemistry. All three cover the various principles of biochemistry in a traditional manner.

Throughout these texts relevant examples and applications from the health science fields are described. Forney gives the most applications, with Holum a close second. The Fessendens' use of relevant examples is more judicious and certainly more than adequate.

Outstanding features of these books include the following. Holum's use of up-to-date relevant examples such as clinical charts and a section on radioimmunoassays. The Fessendens' chapter on molecules in three dimensions is excellent. Forney's discussion of several mechanisms of organic chemistry is commendable because it gives students a rationale for predicting products of reactions.

Weaknesses of these texts include the following. Holum gives very few problems concerning the gas laws and he omits a discussion of competitive versus non-competitive inhibition. His treatment of stereochemistry is very brief. The

Fessendens place the chapter on aromatic hydrocarbons near the end of the unit on organic chemistry. Forney does not include any worked out examples on organic nomenclature and writing structural formulae. Her discussion of stereochemistry in the introductory chapter is much too early.

In summary, the Fessenden text is clear and straightforward. It emphasises chemical principles, contains numerous worked out problems and has a modest number of relevant examples from the health sciences. This text is suitable for a course emphasising a traditional chemistry approach. Of the three, the Holum text has the best blend of worked out problems, relevant examples and chemical principles. It would be suitable for a course requiring a

modest degree of mathematical problem solving, a short treatment of organic chemistry and a lot of relevancy. Forney's text is written at a high level and is demanding of the student(s). It would be suitable for a course that emphasises the chemical principles involved in physiological processes and requires only a modest amount of mathematical problem solving. For our two-semester course designed primarily for students in our Nursing Education Program I would prefer the text by Fessenden and Fessenden. □

A.D. Cooper is Associate Professor at the Department of Chemistry, Worcester State College, Massachusetts.

Physical chemistry for biologists

Verne N. Schumaker
E. Reisler

Physical Chemistry and its Biological Applications. By Wallace S. Brey. Pp.589. (Academic: New York, San Francisco and London, 1978.) \$15.95.

SOME, but no detailed knowledge of calculus is required for the study of this text, designed to present the basic principles of physical chemistry with the biologist in mind. The selection of topics is good and the book is easily read. Although the level is elementary, biology majors may find it challenging and it should be considered by instructors who plan to teach at this level.

The first two chapters introduce the kinetic theory of gases, intermolecular forces, Raoult's and Henry's laws, and the colligative properties of solutions. This material expands upon topics usually introduced in first year chemistry courses at about the same level of sophistication. The basic concepts of thermodynamics are presented in the next two chapters. In our opinion these chapters will require much discussion and supplementation by the instructor to impart more than a casual acquaintance with the first and second laws.

A good presentation of the Debye-Huckel theory is given in the chapter on solutions of electrolytes. The elementary algebra of ionisation and titration of weak electrolytes comes next, followed by a

chapter on oxidation and reduction. Biological applications are described mostly in qualitative terms. The electromagnetic and quantum nature of radiation is used to introduce a simple exposition of the photoelectric effect, the Bohr atom, particle spin, and the structure of polyatomic atoms. The chapter on quantum mechanics ends with a presentation of the Schrödinger equation.

The discussion of bonding and molecular spectroscopy is a descriptive overview of these important areas of physical biochemistry. The explanation of covalent bonds is based on the concept of MO, but the LCAO method, although employed in the text, is never explicitly described. Whenever specific examples are used to clarify the introduced concepts (hybridisation of orbitals, electron delocalisation, vibrational spectroscopy) the presentation is clear and helpful. Fluorescence, for all its potential uses in biochemistry, is hardly mentioned. Circular dichroism, though more popular nowadays than ORD, receives less attention than the latter. The qualitative explanation of these techniques is clear, though it lacks somewhat the continuity of presentation.

The chapters on Kinetics of Chemical Reactions and on the Adsorption and Surface Effects are well written. Though brief, these sections focus the attention on areas of great significance. Transport methods and light scattering are described in the chapter on macromolecules. Specific examples or additional illustrations would have helped in giving the students a better feeling for how the actual experiment is conducted, and the data collected and calculated. □

E. Reisler and Verne N. Schumaker are affiliated with the Molecular Biology Institute at the University of California, Los Angeles.

Introductory biology texts

Edward C. Cox & Robert M. May

Biology. By Karen Arms and Pamela Camp. Pp.970. (Holt, Rinehart and Winston, 1979.) \$17.95. *Life on Earth*. Second edition. By Edward Wilson *et al.* Pp.846. By A.M. Winchester. Pp.331. (Brown: Dubuque, Iowa, 1979.) \$10.95.

IN the US, there are around 3,000 colleges and universities, ranging from local, 2-year junior colleges to the 100 or so major research universities. The array is, moreover, a multi-dimensional one; entry standards vary widely, and some of the small colleges produce very little research yet do some of the best teaching, while some of the great research universities tend to process, rather than teach, all but a few of their students. This enormous and healthy diversity means that introductory biology courses are taught at many different levels, and college texts are competing in a multifaceted niche space. This is reflected in the character of the introductory biology texts reviewed here.

With differences in tactical detail, all seven books share a common strategy for organising the material. This "little-to-big" strategy begins with the rudiments of chemistry and molecular biology, and proceeds to cellular, organismal and population biology, ending with discussion of human ecology. We now comment briefly on the individual books (taking them in what we judge to be descending order of sophistication), and then air some general opinions.

The book by Arms and Camp is the longest (970 pages of double-column small print) and most consistently scholarly of the seven. The authors explain their aim is

to write a comprehensive text without the usual heavy emphasis on molecular biology, giving a fair share of attention to plants, adaptation and ecology; plants, particularly, tend to get short shrift in introductory texts, as instanced by the other six books here. Arms and Camp's *Biology* has six main sections, beginning with cells, and going on to information coding and transfer, taxonomy and discussion of the major phyla, animal biology (mainly physiology, with two excellent chapters on neurobiology), plant biology, and ecology and evolution. The information is up to date (for example, Chapter 9 treats recent work on recombinant DNA, and ends with two incisive essays on protein sequencing and evolutionary trees), and the many illustrations are cogent. The section on ecology and evolution is comprehensive enough to serve as a text for a basic course specialising in that subject, a claim that could not be made for any of the other books.

Generally, Arms and Camp's *Biology* has an air of authority (surpassed only by the high points in *Life on Earth*). The book is also a well designed learning tool, each chapter beginning with a list of objectives and questions, and ending with a self-quiz, a thoughtful set of "questions for discussion", and references for further reading. One fault is a tendency to excessive codification of organisational structure of the book; this reaches obsessive proportions in the 8-page, double-column table of contents. While one of us (R.M.M.) is greatly addicted to numbering things, it must be admitted that: (AC-1) although pedagogically sound, the practice (AC-2) irritates most students, and (AC-3) is here done in an aesthetically displeasing way. Apart from this minor flaw, and the tendency to excessive compendiousness, the book is an excellent and well balanced text for introductory biology at a good college, covering the field at the right level and in a serious and interesting way.

Life on Earth by Wilson *et al.* is the book we have been using in our own course. The good parts are very good indeed, but (as is hard to avoid with seven authors) the book is patchy both in the topics covered and in the level of presentation. In general, the chapters on cell chemistry, the structure of macromolecules, energetics, population biology and ecology are done well. But parts of the chapters on molecular genetics, classical genetics, and cell chemistry and development are superficial, use metaphors that distract rather than enlighten, or are excessively compressed (sometimes to the point of unintelligibility). The quest for "relevance" is not always fortunate; the two final chapters on alternative futures, "Toward A Stable Ecosystem" and "Defeat by Default", are troughs of insubstantial rhetoric. The book by Curtis has the edge in careful planning, consistent presentation, and crisply appropriate examples from the literature. The strengths of *Life on Earth* are the peaks where people close to the frontier give glimpses that a well prepared student will find new and exciting: the evolution of polypeptide chains; the origins of life on Earth; the molecular details of enzyme action; island biogeography.

Two booklets accompany *Life on Earth*: a *Study Guide* and *Test File*. The *Test File* is simply a compendium of over 1,000 multiple-choice test questions. It is easy to find horrors, but then it almost always is. Chapter by chapter, the *Study Guide* summarises key ideas and terms, gives a quiz for "organizing and testing your knowledge" (which is done well), and gives a sample "self-test". The emphasis is on regurgitating information (as Simon and Garfunkel sing, "All my words come back to me, in shades of mediocrity"), which is not easily avoided in introductory biology texts. Diligent use of these booklets would almost guarantee a student an A in a multiple-choice or short answer examination.

The third edition of *Biology* by Helena Curtis has moved from strength to strength through two substantial revisions. The book has the standard progression from the biology of cells, through the biology of organisms, to the biology of populations. Uniformly, the coverage is thorough in simple and lucid prose, making few assumptions and basing the discussion on the previous chapters. The approach tends to be intuitive, rather than analytical. The book is richly illustrated by spectacular micrographs, colour photographs and excellent graphics. The diagrammatic representation of the Krebs' cycle, for example, uses three colours to lay bare the essentials of the cycle with brilliant clarity. At no point, however, does the book strive for real depth or authority. Beautifully produced and even in tone, it is an extremely good introductory biology text for students who have no extensive science background; but it may lack the spark desirable in a college text for students who

A spider monkey

From *Biology* by Helena Curtis

have a first-rate high school preparation in the natural sciences.

Case's *Biology* is a well written text at the level appropriate for a student with relatively little science background. It begins with chemistry and the beginnings of life, and moves to genetic biology and multicellular life and (briefly) evolution. The second half of the book is devoted to human biology, mainly physiology, with brief excursions into general aspects of population biology and ecology as they bear on human populations and their environmental problems. Various topics are fleshed out nicely by quotations from the original researchers. Among the seven texts, Case deserves praise for making the most substantial attempt to tackle mathematical problems in biology, particularly in quantitative aspects of population growth. The book is well produced (though nothing rivals Curtis). It is broadly at the level of Curtis, differing in giving more attention to human biology and human problems, and less attention to other organisms above the cellular level.

In *Biology, The World of Life* by Wallace, the first 8 pages set much of the tone, juxtaposing scenes from the natural and the man-made world: row houses in San Francisco versus the hills untouched; the northwest face of half-dome in Yosemite versus trash piled in a New York alley; but not, for example, the Taj Mahal versus a naturally oily bog. The basic presentation is thorough, rigorous and well organised in the canonical little-to-big format, but lacking a sense of the excitement of the research frontier. The population biology and ecology sections are at a low level, and are broken up by intrusive moral tales. The illustrations are good, though the graphics are not as good as in the above texts. Much more than any of the other books, Wallace's text conveys a real sense of a characterful individual who really enjoyed writing it. If we must have an author's views on sex or why have children or the sociobiology debate pressed upon us, let it be someone with the sense, sensibility and self-deprecating humour of Wallace. We found his distinctive style to be, in the main, engaging and witty, with occasional lapses into the self-consciously literary or, like, cool ("We've tossed around some heavy concepts fairly loosely here", page 441). The book is designed primarily for students not majoring in biology, which seems right, although if one really warmed to Wallace's idiosyncrasies, one could risk the text on biology majors.

Wallace's book comes with a *Study Guide*, which we think clearly superior to the one accompanying *Life on Earth*. There is some reliance on true/false questions, and on multi-choice, but an attempt is made to get the student thinking as well as mastering detail. The helpful hints (for example, on how to solve genetics problems) seem genuinely helpful.

Concepts in Biology by Enger *et al.* is apparently designed primarily for use in

junior colleges. The chapters on molecular biology and cell structure and chemistry are very simple, but accurate and competently done. Discussion, for example, of photosynthesis, glycolysis and oxidative phosphorylation is to the point and easy to follow. In the absence, however, of a discussion of underlying energetics, the processes lack context and appear arbitrary; a little like memorising Persian. The presentation of organismal biology and ecology is similarly competent, adequately illustrated, but descriptive rather than analytical. The sentences are short, and the general tone seems aimed at an audience with little preparation, not only in science, but in reading or thinking; a random collection of section headings is illustrative ("The environment calls the shots", "Nature throws a curve" (the logistic), "The holey ones — the sponges or porifera", lots of irrelevant cartoons). For the chosen level, the biological coverage is good, but students deserve better prose than this.

The World of Biology by Davis and Solomon is written at a very elementary level. It is given to discussion of the "lifestyle" of organisms, and to "relevance". It also has too many mistakes, which disqualify it as a text. For example, on page 39 it is claimed that radioactive oxygen was used to show that the oxygen in CO_2 appears in glucose, not in free oxygen. Two kinds of experiments were actually done: in one, ^{18}O -labelled water was shown to generate ^{18}O -labelled oxygen by photolysis; in the other, isotopes of carbon, both stable and radioactive, were used to show that carbon from CO_2 appears in glucose. On page 78, the discussion about conformational regulation of enzymes contains a completely misleading example, implying that proteins denature and renature as they go from inactive to active forms within the cell. On page 111, apart from the slangy writing in the first part of the paragraph, it is asserted that 90% of cancer cases are thought to result from environmental factors; this is, to put it mildly, debatable. On page 609, the Scopes trial is claimed to have increased public acceptance of evolution; in fact, its immediate effect was to see references to evolution systematically removed from the next generation of textbooks.

In the table below, we have summarised some of the more mechani-

cally pedagogical features of these books. It must, of course, be remembered that the above list is not an exhaustive list of introductory texts. In particular, the new edition of Keeton will probably be a strong contender in the top category.

Our list of books also included a *Biology Laboratory Manual* by Winchester. This manual sets out 26 different experiments, illustrating many of the chapters in most introductory texts: chemistry; cell movement; seeds; protists; structure of higher plants through animals; the reproductive system; and principles of heredity. For the most part these experiments are purely descriptive, with little emphasis on doing new things or testing unknowns, or the like. We like the chapter on the reproductive system where it is noted (page 296) "Now that we have gotten away from some of the mid-Victorian ideas about anything related to sex", "semen can be collected in a condom during sexual intercourse" for this part of the laboratory. The manual offers no advice, West-Coast-contemporary or otherwise, on who supplies the sample.

Looking over this set of books, as a whole, prompts several thoughts.

The subject matter embraced by biology has grown, and continues to grow, at a prodigious rate. There is an inevitable tendency to gargantuan texts, overwhelming the student with detail and anecdote. One way of coping with this problem is to be selective in the coverage, but as a publication strategy this carries the danger that opinionated reviewers will complain about patchiness, as we have about *Life on Earth*. Another idea, easier said than done, is to focus on a few organising themes and general questions. For example, the question of why are there as many species as there are — a few million rather than billions or thousands — has nagged the seminal thinkers from Darwin to our day. Much of the material on ecology, phylogeny and the fossil record can be organised around this theme, but ultimately our ignorance about the answer to the question makes for a fuzziness that most students find uncomfortable (which is, presumably, why none of the books develops this particular theme). As another example, why do most ecosystems have only three or four trophic levels? A limited number of studies in the 1950s suggested 10% of the energy at one level flows to the

Pedagogic characteristics of the seven texts

Authors	Objectives listed at start of chapter?	Summary at end of chapter?	Glossary of technical terms?	Questions at end of chapter?	References for further reading?
Arms & Camp	Yes	Yes	Combined with index	Yes	Yes
Case	No	No	Combined with index	No	No
Curtis	No	Yes	End of book	Yes	Sometimes
Davis & Solomon	Yes	Yes	Start of chapter	Yes	Yes
Enger <i>et al.</i>	Briefly	Yes	End of both chapter and book	Yes	A few
Wallace	No	Study guide	End of book	Study guide	Yes
Wilson <i>et al.</i>	No	Study guide	End of book	Study guide, Test file	Yes

next, which gave rise to the answer that such attenuation necessarily limits the number of trophic levels to a few. But subsequent work has shown the percentage of energy transfer varies widely among terrestrial and marine communities, and between warm and cold blooded animals, yet the number of trophic levels remains remarkably constant at around three or four (with a tendency to fewer, not more, levels in highly productive environments). Here is a fascinating question, of importance and relevance. Yet only two books (Arms and Camp, and Wilson *et al.*) raise the question as such, and both answer it with the conventional wisdom of the 1950s. All seven books assert the "10% law", and the *Test File for Life on Earth*, indeed, offers a multiple-choice question in which the "correct" answer is that 10% of the energy at one trophic level is transferred to the next, with 5% or 2% being wrong answers; this is fossilised misinformation. In short, the larger questions tend to be lost, and replaced by detail.

The mathematics in these books at most extends to simple algebra and the exponential function. The student is asked to understand the simple mathematics of the Hardy-Weinberg theorem in five of the books (Davis and Solomon mention it, Case does not), but population genetics is

not further developed. It is hard to see how things could be otherwise, given the low and systematically declining (witness the SAT scores) mathematical preparation of students entering college in the US. At the same time, description continues to give way to analytical approaches in biological research, and the gap between what is needed and what we teach in elementary courses continues to widen. There is no easy answer.

With the exception of Arms and Camp, and Curtis, all the books, to one degree or another, preach to their audience about matters to which the authors bring no special qualifications. The classroom setting encourages this self-indulgent evangelism about sex, lifestyles and man's environmental problems, to the point where it constitutes a form of occupational hazard. But there is less excuse for allowing such material to pervade an introductory biology text, much less allowing it to provide the central theme. Examples are Wallace devoting more space to foreplay (2 pages) than to food chains (1 page), Case more or less equating ecology with human ecology, David and Solomon giving as much space to examining yourself for breast cancer as to the history of ideas about evolution, or the discussion of reproduction in *Life on Earth* degenerating into

chatter about Harris' *My Life and Loves*. Relevance is the grail that justifies all this. The pity is that biology in general, and population biology and ecology in particular, offer much scope for the pursuit of important and relevant problems, in a substantial way that lies within the framework of the discipline. Our bad-tempered remarks stem from the belief that the most important goals of college education are to introduce people to sustained and dispassionate analysis, and to teach them to distinguish hard fact from casual opinion; the books do not all serve this cause well.

Finally, notice that the seven books illustrate a form of law of one price. Apart from the paper-bound Enger *et al.*, the books all inhabit the range \$16.50 to \$20.00. The absence of niche segregation by price is understandable, although remarkable in view of the disparities in size, quality of production and quantity of professional effort among the books. □

Edward C. Cox is Chairman of, and Robert M. May Professor in, the Biology Department at Princeton University, where they jointly teach an introductory biology course.

Physics for poets

A. M. Sachs

Physics Without Math: A Descriptive Introduction. By Gilbert Shapiro. Pp.351. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$14.95. *The Ideas of Physics.* Second edition. By Douglas C. Giancoli. Pp.528. (Harcourt Brace Jovanovich: New York, 1978.) \$14.95. *Physical Science: A Dynamic Approach.* By Robert T. Dixon. Pp.402. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$15.95. *Conceptual Physics . . . A New Introduction to Your Environment.* Third edition. Written and illustrated by Paul G. Hewitt. Pp.660. (Little, Brown and Company: Boston, 1977.) \$15.95. *Instructor's Manual to Accompany: Conceptual Physics . . . A New Introduction to Your Environment.* Third edition. By Paul G. Hewitt. Pp.245. (Little, Brown and Company: Boston, 1977.) Free.

THE four books will be considered here as texts for an elementary and usually terminal physical science course for non-science college students, who often refer to it as physics for poets. (Giancoli's and Hewitt's books are also intended, as

Hewitt states, "as a springboard to a greater involvement in physics".) Although this reviewer is presently teaching such a course, he has neither used these texts nor had the opportunity of observing the reaction of students who have read them. On a larger scale, it is unlikely that any text will gain widespread acceptance in this area, since each teacher seems to have his own ideas in particular as to how a physics course for liberal arts students should be designed.

These four books explicitly avoid mathematics and either under-emphasise or omit entirely quantitative problems. In *Physics Without Math: A Descriptive Introduction*, Shapiro states that "it is possible to learn about the scope and power and, yes, beauty of a scientific explanation of nature without solving equations". It is possible, perhaps, but the question could be raised as to whether the psychological gain for some students with "built-in bias against science" is worth the verbal complication for others in his statement, for example, of Kepler's third law: "The ratio (distance times distance times distance) divided by (period times period) is the same for all planets." Giancoli in *The Ideas of Physics*, does use equations in the text and gives some derivations in footnotes, and — presumably to broaden the prospective market — indicates that an "Optional Mathematical Supplement" is available.

All the books cover broad areas of physics, with a varying proliferation of topics. In common with most introductory physics texts, there is little continuity between sections. The second half of Dixon's book *Physical Science: A Dynamic Approach*, is devoted to a survey of chemistry, geology and astronomy, so the 200-page coverage of most areas of physics in the first half is probably too superficial for a course devoted entirely to physics. Giancoli's book and Hewitt's *Conceptual Physics . . . A New Introduction to your Environment*, follow the conventional order and exhaustive list of topics of traditional texts, including fluids, sound and geometrical optics, as well as introducing relativity. Shapiro does not hesitate to omit some topics entirely and to skip over the details of others, while concentrating on introducing enough physics to permit discussion of major areas such as energy and the 'frontiers of science'.

All the authors stress to some extent the historical development of science, as, for example, in the familiar treatment leading from the description of planetary motion to the formulation of newtonian mechanics. Shapiro and Giancoli are a little more consistent in maintaining a historical perspective, but most of the references after the eighteenth century are primarily to names and dates.

Shapiro is concerned with the basic

concepts of physics; a limited number of specific phenomena are described, primarily as examples of these concepts. Hewitt is more directly concerned with 'how things work' and describes, somewhat superficially, many devices such as an aneroid barometer, microelectronic circuits, a ruby laser and a fluorescent light. Giancoli takes more of a traditional approach, stressing important concepts but with a tendency toward describing a wider variety of phenomena.

The four books vary considerably in their scientific sophistication, the liveliness of their presentation and the visual appeal of their format. Shapiro's book displays a deep understanding of physics, with a number of unconventional approaches such as introducing mechanics through the concept of energy and defining force, pressure, surface tension and torque as ratios of "energy transferred" to distance, volume decrease, surface increase and angle, respectively. A serious student can gain significant insight from the book, especially if guided and reinforced by an

accompanying course; less intensive reading of the book, however, is likely to lead to little more than a familiarity with the vocabulary. Unfortunately, the formal tone of exposition and the lack of liveliness in the illustrations and format make it unlikely that most non-science students will be spontaneously attracted to the book.

The visual features of Giancoli's book, on the other hand, are unusually attractive. There is an abundance of lively, and often humorous, two-colour illustrations, imaginatively designed to attract attention as well as to give insight into physical principles. The pedagogy and organisation of the text are more conventional, except perhaps for a series of "experiment-projects" to be performed independently by the students. The book attempts to cover a very large number of topics by presenting and discussing results usually without derivation. For a 'physics for poets' course, it would seem preferable to treat a limited number of topics in greater depth.

Hewitt's book has some of the same visual advantages as Giancoli's. In its 650 pages, however, it tends to be even more encyclopaedic, while consciously being even less quantitative. I fear that its admirable (but not subtle) attempt to relate to students with scientifically disadvantaged backgrounds will unfortunately backfire for most liberal arts students. Some of its chapters start with full-page photographs of children with comic-strip-like 'balloons' containing expressions such as "man-o-man-you should've seen the wild spills I used to take before I got into wide wheel bases", before the chapter on rotational motion. The imagination and humour in the book's many small illustrations seem appropriate for all students; the occasional use of a less mature approach and vocabulary may give many students the impression that the author is talking down to them. □

Introductory meteorology

Ira W. Geer

Fundamentals of Meteorology. By Louis J. Battan. Pp.321. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$14.95. *The Atmosphere: An Introduction to Meteorology.* By Lutgens and E. Tarbuck. Pp.413. (Prentice-Hall: Englewood Cliffs, New Jersey, 1979.) \$14.95. *A Basic Meteorology Exercise Manual.* Revised edition. By Chelius and Frenz. (Kendall/Hunt: Dubuque, Iowa, 1978.) \$7.95.

THE three publications reviewed here are intended for introductory college-level courses in meteorology for students not majoring in the atmospheric sciences.

By far the best of those examined is *Fundamentals of Meteorology* by Battan. Clearly written and highly readable, it treats topics found in most introductory weather texts and includes chapters on atmospheric optics and acoustics, and weather applications. Reflecting the author's background and interests, frequent referral is made to basic physical principles and relationships which in turn provide the foundation on which subsequent descriptive information is based. Various aspects of air pollution are presented in ways which will no doubt enhance student interest in a number of topics discussed. The book is relatively free from typographical errors or mistatements. However, one is the mention of South Atlantic hurricanes, when hurricanes in the southern North Atlantic

Ocean was obviously intended (page 183). This book is recommended without reservation for use as a course text, a handy teacher reference, or just plain good reading.

The Atmosphere by Lutgens and Tarbuck was an attempt to write a non-technical and non-mathematical treatment of weather and climate. It seems to be geared to the reading and interest levels of the poorly prepared student. Despite the good intentions of the authors, the book fails miserably. It is lacking in scientific accuracy and quality of writing. The concept of (air) pressure is frequently equated to force (pages 10,121,122 and 124). This leads one to conclude that the authors fail to demonstrate an understanding of basic physics, let alone its applications to the atmospheric environment. Statements about "the infinite universe" (page 1) and that "air condenses" (page 233) illustrate the multitude of errors which at best can be called sloppy writing. Simply stated, the book cannot be recommended for any purpose.

A Basic Meteorology Exercise Manual by Chelius and Frenz is "for students of basic meteorology to be used as a supplement to a lecture course or used in an independent laboratory course". Twelve exercises are presented on topics entitled Temperature, Moisture, Winds and Pressure, Clouds and the Precipitation Process, Fronts and Extra-Tropical Cyclones, Upper Air Flow, The Thunderstorm, Climatology, Air Pollution, Weather Radar, Weather Forecasting I and Weather Forecasting II. The bibliography contains a brief list of books and other sources of information.

The manual's sections touching on

satellite imagery, air pollution, weather radar, the relating of surface to upper air weather features, and weather forecasting are somewhat unique as they are not typically treated in the few other basic manuals available commercially. They add a great deal to a publication which is weak in terms of its layout and the quality of its narrative portions. Statements such as "the condensation of water vapour produces precipitation" (page 15) and the description of saturated air as being "like a sponge that can hold no more water" (page 19) appear too often. Unfortunately, student analysis of data from actual atmospheric observations is not often called for. In its present condition the manual cannot be recommended for course adoption. Teachers might find a copy useful for ideas they might want to develop on their own. With considerable revision, the manual could become suitable for general use. □

Chemistry for the non-science student

A.P. Zipp

Inside Chemistry. By Charles Compton. Pp.569. (McGraw-Hill: New York and London, 1979.) \$16.95.

IN the words of the author, this text was written to "meet the special needs and interests of nonscience students" while having enough flexibility to "provide the basis for courses with different emphases, levels and lengths". In my opinion he has been reasonably successful in achieving his goals, although the book has limitations.

On the positive side, the selection of topics seems sufficiently broad to satisfy most instructors, although several lack depth (see below). The text is divided into eight chapters (297 pages) of 'core' material and seven chapters (200 pages) of

'applied' topics, with each of the latter being independent of the others so that they may be studied in any order or combination. In addition, most chapters contain optional sections and the bulk of the quantitative material has been gathered into supplements at the end of the text. These features should allow each instructor to adapt the book to his own course.

The book is written at an appropriate level and the examples used should be of interest to the intended audience. The learning process should be enhanced by the self-study questions (with answers), the practice exercises (without answers), and the key word lists which follow each chapter as well as the excellent glossary at the end of the text. The data and statistics are as current as could be expected, a point which is particularly important for environmental courses, and each chapter has a list of relevant references (some as recent as 1977).

On the negative side, the book is occasionally redundant, although this occurs mostly in the later chapters which are intended to be independent of one

another (for example, photosynthesis is discussed in three different places and production of carbon monoxide in two). More seriously, some discussions lack sufficient depth to be understood readily. Specific examples include Dalton's atomic theory, the greenhouse effect, base pairing in nucleic acids, oral contraceptives, and amino acid balance in foods. Although this can be remedied in lecture, it may be distressing to students who consider a text to be the final authority, and instructors who feel similarly may wish to select a book designed for a course with a particular emphasis (for example, environmental or biochemical).

In summary, this is a potentially useful text with enough strong points to justify its consideration by instructors of non-science major courses but should be recognised as one which will require supplementary work by the teacher in many areas. □

A.P. Zipp is Professor of Chemistry at the State University of New York at Cortland.

Aquatic insects

A.A. Grigarick

An Introduction to the Aquatic Insects of North America. Edited by R.W. Merritt and K.W. Currins. Pp.441. (Kendall/Hunt: Dubuque, Iowa, 1978.) \$21.95.

AQUATIC insects have been receiving a great amount of attention from many scientific disciplines for the past 20 years. During this period a considerable number of taxonomic changes, new information on distribution, and ecological studies on aquatic insects have occurred. Merritt and Cummins have gathered the contributions of an impressive group (21) of scientists to incorporate much of this information into *An Introduction to the Aquatic Insects of North America*. The book was directed at both students and professionals of the many fields that deal with the aquatic habitat and the authors do not assume the reader to have an entomological background.

The first chapter explains the make-up of the book, indicates its limitations and presents an annotated list of general taxonomic references dealing with aquatic insects. Enough general morphology is given in Chapter 2 to lay the groundwork for use of the keys. Chapter 3 is devoted to collecting, sampling and rearing methods which are tabulated by habitat and community. This chapter includes an amazing amount of information in a well organised and concise form and it is well documented with source material and illustrations.

A short chapter on ecology and distribution sets the format for the handling of this information in later chapters at the generic level in each order. The tabular presentation of information includes habitat classification, locomotive behaviour, trophic relations (based on feeding mechanism) and distribution. By necessity, this information is often based on generalisations of limited numbers of species but when it is used in this light and with the supporting references it is of considerable value. In table 4C some of the examples of orders used to demonstrate trophic classification and columns of the classification are either out of alignment or wrongly set up at the printers. The reader should obtain this information directly from the trophic relationships presented at the end of the chapter for each order.

Phylogenetic relationships and evolutionary adaptations of aquatic insects are briefly reviewed in Chapter 5. Chapter 6 takes up the entomological basics of classification and metamorphosis and a key to immatures and adults is given for the orders with aquatic or semi-aquatic insects. These orders are taken up in a phylogenetic sequence in the remaining chapters. A general introduction, pertinent external morphology and keys to the family for immatures and adults are given for each order. Key characters are usually well illustrated and additional taxonomic references follow the keys. Each chapter concludes with a tabular summary of ecological and general distributional information at the generic level.

The keys to Megaloptera, Neuroptera and Lepidoptera (in part) allow identification to genus. About one-third of

the book deals with the aquatic Diptera and includes separate chapters on the Tipulidae, Culicidae, Simuliidae and Chironomidae. The expanded treatment of these families includes keys to immatures and adults to genus for the first three but is limited primarily to tribe for the chironomids. The limitation of the taxonomic treatment to the family level for most orders was disappointing to many researchers and instructors of courses in aquatic entomology. With due respect to the large size of this group of organisms and incomplete knowledge of some taxa (for example, Diptera), the taxonomic information for identification to the generic level has been developed for most families. Identification to genus would certainly be desirable in this book and would appear to have been possible if a comparable amount of effort had been made in this direction as was devoted to summarising ecological information to genus.

As the title states, the region of this book's coverage is North America. However, the great diversity of aquatic insects in North America (over 10,000 species), the degree of ecological coverage, excellent illustrations and extensive source material (1,712 references) make this book very useful to aquatic biologists throughout the world. It is particularly welcomed by instructors of the subject. □

A.A. Grigarick is Professor of Entomology at the University of California, Davis, California.

13 March 1980

Dioxin and 2,4,5-T: what are the risks?

A court case due to take place on Monday will decide for, or against, the use of the herbicide 2,4,5-T in the United States. Two old adversaries, the Dow Chemical Company and the Environmental Protection Agency, will argue the case over the legality and validity of the partial ban on 2,4,5-T currently in operation in the US. Dow Chemical, the largest manufacturer of 2,4,5-T in the world, will challenge the ban imposed by the EPA in March of last year; it is Dow's view that 2,4,5-T poses no risk to users.

There are those in the EPA who now believe that Dow will win the case. The Agency's own study linking 2,4,5-T spraying with an increase in spontaneous abortions in the state of Oregon — information on which the decision to ban the herbicide was based — apparently has serious flaws. The study has been severely criticised on methodological grounds by many independent scientists, and at least three reports have been produced opposing the EPA's findings. They argue that the areas of land chosen in the original EPA report were not carefully matched and therefore could not be regarded as truly representative of a 2,4,5-T sprayed area and control area. In addition, differences in hospital admissions for miscarriages vary among the regions chosen for study, and these practices, critics charge, were not given due consideration in the original study.

Such criticisms may be justified, and a reappraisal of the Oregon study, taking these additional factors into account would probably remove the association between miscarriages and 2,4,5-T spraying.

Evidence that the EPA is indeed moving away from a reliance on the Oregon study is provided in the Federal Register of 13 December, 1979. The Agency now appears to be basing its decision to call for a total ban on 2,4,5-T on the fact that the 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) contaminant present in the herbicide is an established animal carcinogen. Many oncologists now consider that there is no safe threshold dose for a carcinogen, and the EPA considers, therefore, that to expose the public to such a chemical by permitting usage of 2,4,5-T poses an unacceptable risk.

There are many in the EPA who believe, however, that in spite of the presence of dioxin in 2,4,5-T there is still no hard evidence of a health risk from the herbicide. A recent request from Dow Chemical under the Freedom of Information Act for all of the EPA's documentation on 2,4,5-T could well provide confirmation of the lack of this evidence. If Dow's request is

granted, the EPA's case for seeking a permanent ban on the herbicide could well be undermined.

Evidence elsewhere against 2,4,5-T is not very strong either. The best study to date was completed in Sweden and produced evidence that among those exposed to 2,4,5-T and chlorinated phenols in the course of their work in the lumber industry, there was a six-fold increase in soft tissue sarcomas. But even in this study confounding factors may not have been taken fully into account and the Swedish government is reassessing it.

It is therefore quite clear that more good and reliable data need to be collected for a proper assessment of the hazards of exposure to 2,4,5-T and its contaminant, dioxin. The best place to seek such data is in the medical records of those who have been or will be involved in the manufacture of 2,4,5-T, since they are most likely to be at risk. In particular that is so because dioxin, which poses the greatest potential hazard, is generally present in larger concentrations during the manufacture of 2,4,5-T than during its use. And to conclude that 2,4,5-T is safe to use without reviewing the full evidence on industrial exposure, as did the UK Ministry of Agriculture, Fisheries and Food last March, is distinctly unsound.

At present the available industrial data are limited and concentrate on exposure after accidents. There is some evidence for a clustering of gastro-intestinal cancers among BASF workers who were exposed to dioxin in an accident in West Germany in 1953, and for an increased rate of heart attacks after an industrial accident in Amsterdam at the Philips Duphar plant in 1963. Monsanto have studied the after-effects of a 1949 accident, and concluded that among affected workers there was a normal incidence of cancer and a lower than normal incidence of heart attacks (*Nature* 14 February, page 613).

More industrial data are needed and must already be available both from the UK firm of Coalite and Chemical Products Ltd., whose reluctance to reveal its data we reported last week, and elsewhere. It is therefore essential that Coalite should reveal the study it has already done and conduct further studies using proper controls and including all those exposed to dioxin whilst in its employment. And when it has done so it must pass the data on to the two bodies which are accumulating a world data-base on 2,4,5-T: the US National Institute of Occupational Safety and Health and the International Agency for Research on Cancer. Only when good studies are complete and openly available can the air be cleared for or against 2,4,5-T. □

United States

Pressure mounts to resume chemical weapons production

REPORTS of the use of poison gas by Soviet troops in Afghanistan are being used to help generate support for allowing the US military to resume the production of chemical weapons banned since the late 1960s.

Supporters of such a move argue that there is considerable evidence that the Soviet Union already possesses a chemical warfare capability considerably superior to that of the US — and that the reports from Afghanistan indicates its willingness to use it.

Critics, however, argue that many widely-quoted estimates of the Soviet stockpile of chemical weapons are greatly exaggerated, and point out that there is as yet no confirmed evidence that Soviet troops have used anything more than riot control agents against Afghan forces.

The US army has been pushing for several years to proceed with production facilities for a new generation of so-called binary weapons, in which two non-lethal gases combine on firing or impact to form a deadly mixture. Such weapons have been under research since the mid-1960s.

Congress rejected this proposal in both 1974 and 1975. More recently, plans for \$111 million production facility was cut by the White House from the Defense Department proposed budget for the fiscal year 1981, currently before Congress.

But pressure is building for the proposal to be reinstated. And at the same time, the Pentagon is increasing the scope of the plans that it would like to put into effect. In January, Defense Secretary Harold Brown announced that, whereas previously it had been intended only to produce projectiles containing the two gases, plans are now being drawn up for producing binary bombs and warheads as well.

Last week the possibility of moving to production came even closer when William Perry, Defense Under Secretary for research and engineering, signed a memorandum instructing the department to complete designs for such a facility and draw up a construction schedule.

How sympathetic Congress is likely to be towards a request for funds for this purpose remains unclear. But a considerable number of articles have appeared in the US press in recent weeks focusing both on the claims about the use of poison gas in Afghanistan (which even the Central Intelligence Agency, after careful study, is said to have been unable to confirm), and more broadly on the apparent inferiority of the US's chemical weapons capability.

An article in *Time*, for example, states that "without a credible chemical counter-punch, it becomes more likely that the US

would have to resort to tactical nuclear weapons as a response to a Soviet attack".

Dr Matthew Meselson, professor of biology at Harvard University and a long-time opponent of chemical and biological warfare, claims that many of the current estimates — such as one that the USSR has a stockpile of 350,000 tons of chemical weapons, compared to only 42,000 tons in the US — are unrealistic and based on faulty speculation, even according to some Defense Department calculations.

"I am concerned that making policy by excitability is likely to lock us into a series of policies which are unwise from a defence point of view, since I do not think that

chemical weapons are that useful in combat situations", Dr Meselson said last week.

The pressure to reintroduce chemical weapons production has coincided with the latest round of chemical disarmament talks between the US and the USSR in Geneva. At the end of the last round in August 1979, US officials expressed optimism that real progress towards an agreement banning such weapons was beginning to be made.

Some now argue that, if the US steps up its production, this will provide added pressure for an agreement. Others, however, argue that it could create a new stumbling block to the negotiation. □

Princeton and Saudi universities sign life sciences agreement

PRINCETON University and the University of Riyadh in Saudi Arabia have signed an agreement under which each university will assist the other to build up a centre for training and research in the life sciences.

The Saudi Arabian university will donate \$5 million to Princeton, a substantial proportion of which will be used to modernise facilities in the university's Moffett Biological Laboratories, and the rest of which is likely to be used to support a number of new faculty posts in the biology department.

In return, Princeton has agreed to help the University of Riyadh to build up graduate and postdoctoral training and research facilities in the life sciences. This will be done both by advising on course curricula and the selection and training of personnel, and assisting with any necessary technical advice.

The agreement was signed in Riyadh last week by Princeton president Dr William G Bowen and the president of the University

of Riyadh, Dr Mansour Al Turki. It follows five years of negotiation between the two universities leading to what is believed to be the biggest single grant from an oil-producing state to an American university.

Dr Edward Cox, Chairman of Princeton's Biology Department, told *Nature* last week that the money would be used to provide additional support for fields of research, such as developmental biology, in which the university already has a strong research tradition.

Faculty members are currently debating the best way to use the new funds to support research salaries. "One view is that you could use the money for assistant professors, because it is the young people who are most in need of jobs", Dr Cox said. It might be possible to offer a number of five or six year fellowships.

In return for the financing, the biology department will assist the University of Riyadh to set up an international life sciences centre for postgraduate students and postdoctoral fellows, most of whom now have to travel abroad to receive their research training.

Several previous attempts to establish cooperative agreements between US universities and Middle East countries have stumbled over the refusal of the latter to accept non-discrimination clauses — leading to the fear that women, Jews and other minority groups might be excluded from participation.

The two universities have circumvented this problem by agreeing that scholars, technical experts and students will be proposed and received for exchanges "on the criterion of merit" rather than according to any other consideration.

David Dickson

"No!! We won't be needing any cheer leaders!"

Research agencies prepare to tighten budget belts

MAJOR cuts in the US science budget which could virtually eliminate any real growth in research funding over the next eighteen months are expected to result from President Carter's moves to reduce federal spending in an effort to lower the rate of inflation.

No cuts have yet been officially decided. But the President is expected to make public within the near future how he intends to move towards a balanced budget by eliminating about \$4 billion of federal expenditure in the current fiscal year by cutting back on commitments already made, and \$15 billion in the 1981 fiscal year which begins on 1 October by reducing the budget request to Congress.

Virtually the only area expected to emerge unscathed is the defence budget. And since the science budget is an area of discretionary expenditure — unlike social security, for example, where expenditure is mandated by law — it can expect to shoulder a fair part of the burden.

Research agency heads were asked last week by the Office of Management and Budget (OMB) how they would meet given targets for reducing expenditure. Among the cuts under discussion are thought to be:

- National Institutes of Health: OMB has asked for cuts of \$170 million in the rest of the 1980 budget, and \$340 million (about 10% of the total) in the 1981 budget as part of a \$700 million reduction for the Department of Health, Education and Welfare.

One immediate casualty could be the administration's attempt to maintain the number of new competitive research grants at about 5000. This may be reduced to about 3,500, considerably raising the necessary quality of applications likely to be funded. There would also be a general cutback across the whole range of NIH's research activities, possibly resulting in the loss of some scientists' jobs.

- National Aeronautics and Space Administration: OMB is said to have asked NASA to prepare for cuts of \$760 million, a sum equivalent to 14% of the civilian space budget. This would affect almost all of the NASA's programmes, in particular the launch of the space shuttle.

Various planetary missions, such as the Galileo launch to Jupiter, and the solar-polar mission to be carried out jointly with the European Space Agency, would have to be put back, and perhaps even eliminated. The gamma ray observatory, recommended as a new start for 1981, may also be affected.

- National Science Foundation: cuts in the order of \$90 million to \$100 million — about 9% of the proposed 1981 budget — are under discussion with OMB. The budget office has suggested that where possible basic research expenditures should be protected. The main impact is therefore likely to fall on areas such as applied

science and science education.

- Department of Energy: several large-scale energy research projects have to be abandoned or cut back. Among those being closely studied last week in solar energy, for example, were the "power tower" under construction at Barstow in California, and the Ocean Thermal Test Facility (OTEC), now nearing completion off Hawaii.

- National Bureau of Standards: OMB has asked for cuts of about \$7 million, and bureau officials have indicated that at the top of their list is likely to be a new \$5 million initiative to enhance basic research in the agency, a package of eight proposals included in the original 1981 budget request with the specific endorsement of

the Office of Science and Technology Policy.

Administration officials stressed last week that most of the potential cuts were still under negotiation. But President Carter warned state and city officials visiting the White House to expect some unpleasant surprises in the near future — and discussions were taking place last weekend to put together the final package.

If the cuts are made as expected, then they are unlikely to be strongly resisted by Congress, particularly in an election year when many voters will be looking for signs of financial stringency, and to oppose the cuts would be to oppose the President's anti-inflation strategy.

Environment

Lowland tropical rainforest destroyed by road building in the Amazon Basin.

World Conservation Strategy sets priorities for global resources

THE latest international environmental initiative was launched simultaneously last week in 32 countries, amid hopes that the time is ripe to stop squandering the Earth's natural resources. In producing its *World Conservation Strategy**, the International Union for the Conservation of Nature (under the auspices of the United Nations Environment Programme and the World Wildlife Fund) has brought together a wide range of expertise to set out priorities for action to conserve and replenish global resources, from microbial cultures to tropical forests. The heaviest burden of such action would inevitably fall on developing nations, whose will may be impeccable, but whose means may be totally inadequate as the sponsors are bound to admit when they urge policy

makers to take up the strategy.

The major theme of the strategy — that conservation and development must go hand-in-hand has been gathering strength since the UN Conference on the Human Environment in June, 1972. Now the call is for governments and international agencies to base their development programmes on sustainable use of species and ecosystems, which means spending the interest while keeping the capital. The authors of the strategy cite familiar worldwide evidence that much of that capital is being dissipated. Many losses are due to overfishing in the oceans, overgrazing on the land, clearing of forests and destruction of wild animals and plants, often because people are too poor to replenish their resources, even if they take a long term view.

The way to reverse the trend is not by piece meal attempts to save resources once

*Available from the World Wildlife Fund, 29 Creville Street, London E.C.1, £3.60; also available as a book, *How to save the World*, Kogan Page, £2.95 paperback, £5.95 hardback.

they are threatened with destruction. According to the strategy, governments should consider the needs of conservation at all stages of development. As an example, the authors recommend that forestry should not be directed only towards increasing the yield of products and the provision of services such as recreation and education. Forest management must ensure that yields are sustainable, and genetic diversity is preserved. The preservation of genetic diversity in general is an immediate task for governments in order to prevent the extinction of further species of wildlife, crop plants and livestock, any of which could be needed in the future (for example, in agricultural breeding programmes or the production of drugs). The recommended approach is to preserve ecosystems intact within reserves, augmented by collections both of whole organisms, as in zoos and botanic gardens, and of genetic material such as seed and semen.

The preservation of genetic resources is also a priority for action by international agencies, which are called upon to provide a wide range of assistance such as that provided for crop plants by the International Board for Plant Genetic Resources. According to the strategy, financial assistance should also be sought from commercial enterprises that benefit from the exploitation of living resources.

Another international priority is action to halt the depletion of shared resources in oceans and river basins. The scale of losses also makes tropical forests and drylands a priority for international action. In the latter case, low rainfall, high rates of evaporation and inefficient use are encouraging the rapid spread of deserts. The strategy calls for the implementation of the wide ranging plan of action formulated at the UN Conference on Desertification in September, 1977.

The hazards that beset a scheme for environmental action, were well expressed by Mr Michael Heseltine, UK Secretary of State for the Environment, when he said at the launching ceremony in London:

"The basis of my approach — and indeed of the present government — rests on conservation, good husbandry and wise use of resources. But it would be less than frank of me to assert that all decisions of government flow naturally and easily from that premise".

It is, he pointed out, almost always a matter of balancing a developmental need, often with a clear economic advantage, against a potential conservation loss. Mr Heseltine injected a further note of caution when Mr David Attenborough, naturalist and broadcaster, insisted that the people at large should compel governments everywhere to recognise the strategy, which must become a political issue. Otherwise, Attenborough said, it was doomed to be "just another abandoned lofty plan". He has set his fellow citizens a difficult task.

United Kingdom

Fast reactor fuel cycle to begin

THE United Kingdom Atomic Energy Authority has been given approval to make regular shipments of plutonium nitrate in water solution from Dounreay on the north coast of Scotland to Windscale in Cumbria, north-west England, as part of an experimental fast reactor fuel cycle. The nitrate will be the result of reprocessing of fuel elements from the Dounreay prototype fast reactor (PFR). For economic reasons the Authority plans to refabricate new fuel, perhaps by the 'sol gel' process, at Windscale rather than at Dounreay. Shipments will begin later this year, at the rate of one every two to four weeks.

Behind the decision may lie uncertainty about the future siting of the commercial demonstration fast reactor (CDFR) that the Authority would like to build. The government has promised a public enquiry on the fast breeder before any commitment is made to the CDFR, and only if it were to be built at Dounreay would it be economic to build a fuel fabrication plant there.

The shipments ultimately will be on a large scale, involving some 800 kg of

plutonium a year. Each load, carried in a specially designed 250 litre flask in a 27m³ containment vessel, may amount to a critical mass of the metal — so the flask has had to be designed to minimise risk of criticality.

Another design problem has been the continuous radiolysis of water by alpha emission from the plutonium. This results in a build up of hydrogen and oxygen gas, in explosive proportions. An inert gas atmosphere is introduced to dilute the gas, and so reduce the risk of explosion.

"Nevertheless", says a Department of Energy note on the shipments, "assessments have been made of the possible consequences of gas ignition within the package".

The package is unlikely to be damaged in a transport accident sufficiently to breach the inner vessel, says the note. "However, if the vessel was ruptured, and in the further unlikely event that a source of ignition was present, and that the mixture of hydrogen and oxygen was in the explosive range, any resultant explosion internal or external to the containment vessel but inside the outer package would generate insufficient pressure to rupture the external structure."

The inner vessel is designed to withstand the pressure that, it is calculated, will build up in the vessel up to 250 days; then it is unlikely to rupture. The danger here is of a shipwreck, followed by a delay in recovery. The Authority has performed recovery tests on a dummy container hidden in a wreck off West Scotland, which "was found and retrieved in hours". However, tests have not been made on the time for which a damaged inner container (after a collision, say) would withstand pressure build-up.

In an impact test, however, there was cracking of the outer vessel and fracturing of the radiation shield. According to a report prepared by the Nuclear Installation Inspectorate, published last week "it can be argued that would give enhanced access to heat flux" in the case of an impact followed by fire. Although, said an Authority spokesman, "that was one we were a bit bothered about", the NII concluded that thermal tests that had been conducted (on an undamaged third-scale model) were "an adequate demonstration" of safety.

The greatest dangers may occur during the loading and unloading of the inner vessel to and from its impact-resistant container, where the Authority has assumed that the vessel would not survive a two-foot drop. But, says the Department of Energy, the Health and Safety Executive are satisfied, as a result of tests, that the vessel would survive such an impact.

Poland

Bartosiewicz: power cooperation

Energy agreement

MR Zbigniew Bartosiewicz, Polish Minister of Power and Atomic Energy has signed a cooperation agreement with Sir Francis Tombs, Chairman of The UK Electricity Council. The agreement covers the exchange of information and possible joint research on the more efficient use of conventional energy sources for power generation.

The Minister's five-day visit to the UK comes at a time when Poland's industrial expansion programme has outstripped generating capacity.

During his visit, Bartosiewicz attended a seminar organised by the Department of Industry, at which one of the major topics discussed was "down time" — the unscheduled stoppage of generating sets for maintenance work. UK participants in the seminar later reported that they felt the optimisation of maintenance logistics could well be a fruitful theme for cooperation.

High-energy physics

Truce and a German director for CERN

PROFESSOR Herwig Schopper, presently director of the Deutsche Elektronen Synchrotron Laboratory (DESY) near Hamburg, has been designated director-general of the European sub-nuclear physics laboratory, CERN, Geneva. He will succeed the present joint directors-general, Leon Van Hove and John Adams, on 1 January 1981.

The appointment has not been without its drama. The Italian delegation, one of the 12 national representations on CERN's governing Council, had been refusing to accede to Schopper's appointment until possible conflict between future CERN and DESY programmes is resolved. But after an extraordinary statement from CERN and another from the Italian Ministry of Science, the air was cleared last week.

The CERN statement describes the meeting of the Committee of Council on 29 February. The programme for the construction of LEP, the large electron-positron collider which is CERN's next major project, was raised.

The statement said:

"The delegates at the Committee of Council agreed with the Italian delegation that LEP must have the top priority among the European accelerator projects in elementary particle physics, and that it should be built as soon as possible. The delegates also agreed, following an Italian proposal, that a study group be formed to discuss certain legal and budgetary problems and the relation of LEP to national programmes . . .

"The Committee of Council entrusted Professor Schopper with the mandate to present Council, at its session in June 1980, with his proposals concerning the top management structure and the directing staff of CERN . . ."

The 'legal and budgetary problems' refer to the question of whether LEP could be built within CERN's present budget, without declaring LEP as a project requiring special funding. The 'national programmes' referred to mean largely HERA, a proposal at DESY to build an electron-proton collider; its inclusion in the CERN text is something of a coup for Italy, which has been worried that HERA would compete with LEP.

In fact on many issues Germany and Italy have come extremely close, both wanting to push LEP along as fast as possible, at the lowest practical budget.

"I believe we can build the first version of LEP to give beam at the end of 1986", Schopper said on Monday. He will now participate actively in constructing the final proposal for LEP, which will be made to Council in June.

Whether LEP will be a CERN supplementary programme, in which the

participation of individual countries is optional, or part of the basic programme, in which it is not, is a crucial question, Schopper believes. "We must try to activate all sources inside CERN", he said, "and that requires flexibility to transfer people from one project to another". But if LEP is merely a supplementary programme, flexibility will be difficult to achieve.

Schopper thinks that LEP can be built "within a few per cent" of the current CERN budget of SF 590 million a year.

Italy reacted to CERN's announcement with its own statement. The Science Minister, Vito Scalia, said last week:

"... we are finally approaching the solution to defining the programmes of CERN. This has been the aim of the Italian government since November. . .

"For the first time in 25 years, CERN had found itself in difficulties in defining its programme against serious competition from other national laboratories. By the end of last year, the pressures we had been applying to reach a rapid clarification of these problems had had no appreciable result. Council opposed our proposal to

discuss the future of CERN, and the Italian delegation decided to underline its dissent. [The delegation walked out of the December Council meeting, an event unprecedented in CERN history. The meeting was to have appointed Schopper.]

"But last week the Committee of Council demonstrated unequivocally that our action, which was intended to give priority to the discussion of CERN programmes over and above the appointment of a new director-general, was fully justified . . .

"All delegates at the meeting of 29 February have given LEP an absolute priority so the new accelerator will probably be built in five years. This decision allows the laboratory to keep its position of pre-eminence and confirms the validity of the 'active Europeanism' that the Italian government has done its best to promote in international research.

"In view of this development it is clear that the recent solution of the CERN case represents a success for my country . . . It clarifies also why the Italian delegation is now disposed to vote for Professor Schopper . . ."

Robert Walgate

Interferon

US company increases production ten-fold

THE US drug company G D Searle & Co announced last week that it plans to increase its fibroblast interferon production "six to tenfold" by the middle of 1981. Facilities are also being set aside for conjectured production by genetically engineered *Escherichia coli*. A new plant will be built at Searle's High Wycombe, UK, factory.

"But this project is purely for research and development", says Searle's director of research and biological development at High Wycombe, Dr Brian Richards. "It will cost us £6.75 million, and we don't intend to make a profit out of it".

Searle's increased fibroblast interferon production will be supplied to the Anderson Hospital of the University of Texas for clinical tests of the drug in cancer control. The trial has been designed to match an earlier one with leukocyte interferon; it is the first on cancer patients with interferon from fibroblasts, although there has been a successful trial on patients suffering from herpes keratitis of the eye (where the application was external). The difference between fibroblast and leukocyte interferon is not just that they come from different kinds of cells. By several laboratory criteria they also differ in structure. What is not yet clear is whether this will affect their therapeutic value.

Two-thirds of the space in the new plant

will be set aside on a conjecture: that within 18 months strains of genetically engineered *Escherichia coli* will exist which can compete with fibroblasts in interferon production.

"Charles Weissmann in Zurich has produced *E. coli* which manufacture one or two molecules of interferon per cell," says Dr Richards. "I'm quite satisfied he has the right gene product, but the problems are going to come in trying to improve the efficiency."

Searle has in fact constructed bacteria carrying other genes that are expressed with high efficiency — "we have cells producing haemagglutinin at 1% of total protein of the cell" says Richards. Enough is not yet known about expression efficiency to predict whether such bacteria containing the interferon gene in place of the haemagglutinin gene, would be equally efficient, but apparently it gives "cause for hope".

Searle's current interferon production is roughly one quarter of world production, including leukocyte interferon, he estimates. So with the increased fibroblast production alone, world interferon production will increase two or three-fold. "Ultimately costs might fall by a factor of 100 to 1000", Richards estimates. Interferon costs would then be on a par with those of antibiotics.

NEWS IN BRIEF

ESA chooses Hipparcos

THE Scientific Programme Committee of the European Space Agency decided last week to fund the astrometry mission Hipparcos as the next ESA mission after Exosat which is to be launched in 1981. Designed to improve the measurements of stellar positions by two orders of magnitude, the satellite will be launched by Ariane in mid-1986, and placed in a geostationary orbit for its lifetime of two and a half years. The total estimated cost of the project is 139.3 MAU (\$185 million).

Hipparcos was the Programme Committee's final choice in spite of a recommendation by the Scientific Advisory Committee to fund a dual mission consisting of experiments to measure the Earth's magnetospheric tail and a deep space flyby of Halley's comet. By a vote of 10 votes for and one abstention, the 11 member committee, consisting of delegates from each ESA country, decided to overturn the Scientific Advisory Committee's recommendation.

No evidence found of link between saccharin and cancer

No evidence of a positive link between the consumption of saccharin and an increased incidence of bladder cancer has been revealed by either of two studies whose results were published last week. One was carried out by Harvard University's School of Public Health and the other by the American Health Foundation.

The scientists who carried out the study, which involved surveys of the dietary habits of 592 and 367 bladder cancer patients respectively, point out that these results have two possible implications. Either saccharin does not cause cancer; or that its effects are too small to be identified by such studies.

However, writing in the *New England Journal of Medicine*, Dr Robert Hoover, director of a separate study carried out by the National Cancer Institute, states that "the evidence is that little, if any, current bladder cancer is due to the consumption of artificial sweeteners at the doses and in the manner in which sweeteners were commonly consumed in the past."

The Harvard study, reported in last week's issue of the journal, came to the conclusion that artificial sweeteners posed "little or no excess risk of cancer of the lower urinary tract", although pointing out that, since the latency period for cancer due to exposure to toxic chemicals can be 30 to 50 years, it will be some time before definite conclusions can be reached.

The Food and Drug Administration has proposed a ban on the use of saccharin following evidence that it can cause tumours when administered to animals at

high doses. However, the ban was held up by Congress in 1977 until further information about saccharin's effect became known.

Academy report attacked on solar energy predictions

A RECENT report published after four years of study by the Committee on Nuclear and Alternative Energy Systems of the National Academy of Sciences has been attacked for severely over-estimating the costs of developing solar energy as a major source of power — and hence over-stating the need to develop nuclear and coal technologies.

In its report, prepared for the Department of Energy at a cost of \$3 million and subject to some bitter internal disputes, the committee states its conclusion that solar energy "will probably not contribute much more than 5% to energy supply" in the US before the end of the century, at least not without massive government intervention to penalise the use of non-renewable fuels.

This conclusion, however, is being strongly contested by environmentalists, who last year persuaded the Carter administration to commit itself to policies for supporting solar energy research and development designed to meet 20% of the nation's energy needs by the year 2000.

In a letter to the *New York Times*, Gus Speth, chairman of the White House's Council on Environmental Policy, says that as far as he has been able to discover, the committee's estimate that the cost of reaching the administration's target was a prohibitive \$3,000 billion was the result of a "back-of-the-envelope calculation", based on assumptions such as all capital equipment being constructed at today's prices.

Reworking the calculation with declining prices predicted by the committee's Solar Resources Group reduced the cost by a factor of almost three, he said.

A spokesperson for the academy said last week that a reply to the CEQ's charges was being prepared and would be submitted to the *Times* for publication.

Canada appoints new science minister

JOHN ROBERTS, cabinet minister responsible for cultural affairs in Canada's last Liberal government, has been appointed Minister of State for Science and Technology in the new cabinet announced last week by Prime Minister Pierre Trudeau after the Liberal Party's success in the general election.

Roberts will also carry the portfolio of Minister of the Environment. This has disappointed officials in scientific and

professional societies who had hoped that the new government would, like its Conservative predecessor, appoint a minister with sole responsibility for science and technology.

However the Liberal Party has indicated that it intends to make the creation of a strong research and development effort in Canada one of its top economic priorities. An outspoken economic nationalist, Mr Herb Gray, who has been appointed Minister of Industry, Trade and Commerce, said last week that Canada's "disturbingly low level" of R&D expenditure was connected with the high level of foreign control of Canadian industry. Canada's Foreign Investment Review Agency, created in 1974 at Gray's suggestion, will have its mandate extended to investigate the R&D performance of such companies.

Livermore safety report criticised

OFFICIAL reports of "minimal damage" at the Livermore nuclear weapons laboratory from two earthquakes last January were criticised severely last week. Two structural engineers, John Rutherford and Gary Gray inspected the plutonium building where up to 300 lbs of plutonium are stored and described the damage as "severe". A wall had moved during the tremors (the largest of which measured 5.5 on the Richter scale) and it was in danger of collapse.

Friends of the Earth claimed that a big earthquake of the order of 6.5 on the Richter scale could cause a fire which would burn the plutonium causing it to disperse over a wide area in a radioactive cloud.

Dr John Gofman, of the University of California, and a former director of the laboratory, called the Livermore laboratory "a public health hazard". "There is a conceivable possibility of fire and the plutonium burning thus becoming airborne dust. To say, as the officials have, that nobody would be killed is nonsense", he said.

Sakharov vote avoided

THE Russian Academy of Sciences has avoided putting to the vote the expulsion of Dr Andrei Sakharov from its ranks. Two corresponding members of the Academy had proposed a vote but last week were persuaded to withdraw their proposal. Had a vote been forced, it would have taken place in secret and required a two thirds majority to succeed. There is only one precedent for the expulsion of a member of the Academy, and that was of someone whose original election was based much more on political grounds than on genuine scientific achievement.

FEATURES

Swedes vote on their nuclear future

On 23 March the people of Sweden will be voting in a referendum on nuclear power policy. **Wendy Barnaby** writes from Stockholm that the exercise is intended to meet party political rather than major policy objectives

AFTER more than seven years of increasingly acrimonious public debate about nuclear power, nearly all political parties are badly split on the issue and energy policy is totally stranded. Popular support for a referendum was building up at the end of 1978, encouraged by the anti-nuclear Centre Party and various environmental groups, but it was staunchly opposed by the other parties until the accident at Harrisburg. It then became obvious to the leader of the Social Democratic opposition, Olof Palme, that his only chance of winning the general election scheduled for September, 1979 was to about-face and support a referendum.

Faced with a parliamentary majority in favour of a referendum, the minority Liberal party government (which had already tabled an energy bill incorporating 12 nuclear reactors) had no choice but to go along with it as well. The Centre Party and the Communists, also anti-nuclear, argued that the referendum should be held at the same time as the election, but they were overruled by the combined forces of the Social Democrats, Liberals and Conservatives, all of whose leaderships are pro-nuclear, but whose backbenchers and rank and file are split. These parties would have been embarrassed to have their internal disagreements aired during the election campaign. So the referendum was scheduled for March, 1980 — possibly in the hope that the intervening northern winter and the spectre of oil rationing might have a salutary effect on the population's attitudes. (Sweden depends on imported oil for 70% of its total energy consumption, which amounts to a little more than 400TWh a year. Electrical energy, which makes up 90TWh of this, is produced mainly by hydropower. Nuclear power provides 25% of electrical energy; the rest comes from oil).

In the event, Olof Palme's about-face did not win him the election: the bourgeois bloc won with an overall majority of one seat. Nor were nuclear issues prominent in the campaign. They would, it was said, be discussed once and for all before the referendum. But it is clear that the referendum will not be the final curtain of the nuclear drama. It will simply set the stage for another long act.

After the formation of the new bourgeois government (a coalition of the Centre, Liberal and Conservative parties

with Centre leader Torbjörn Fälldin as Prime Minister), the referendum questions had to be drawn up. The party leaderships were divided essentially into two camps: the Communists and the Centre party opposing nuclear power, and the others in favour. But to draw up two alternatives would have meant that the Social Democrats backed the same alternative as the Conservatives. This was politically unpalatable to the Social Democrats, who feared they would lose voters if they were seen to be aligned with the Conservatives on such a crucial issue. They therefore wrote into their referendum manifesto that all power production should be state-owned: not a revolutionary demand, as about 85% of it is state-owned already. As expected, however, the Conservatives could not go along with this, so the pro-nuclear side split into two factions.

As a result of this political face-saving, the voters must now decide between three options. Option three, supported by the Centre and Communist parties, Christian organizations and a variety of environmental and radical fringe groups, advocates phasing out the six reactors presently in operation over a period of ten years, and intensifying energy-saving and investment in renewable energy sources. Option two, supported by the Social Democrats and Liberals, advocates "phasing out nuclear power at a pace possible, taking into account the need for electric power for the maintenance of employment and welfare." In practice, this pace would mean, according to option two, using the six reactors now in operation as well as the four ready for loading and the two under construction — a total of 12 — for their lifetimes (about 25 years), but not building any more.

Option one, supported by the Conservatives and industry, also advocates (in identical wording to option two), "phasing out nuclear power at a pace possible taking into account the need for electric power for the maintenance of employment and welfare". This pace would also mean using all twelve reactors. Officially option one also vetoes building another generation of reactors, but its backers make no secret of the fact that this is written in because it would be unwise to declare their enthusiasm for nuclear power in the present political climate. Option one is generally regarded as being more pro-nuclear and more likely to go ahead with

Two Swedish Prime Ministers: former Social Democrat Olof Palme (left) switched to supporting the referendum against his party line. New Centre premier Torbjörn Fälldin (right) is anti-nuclear, but could not implement an anti-nuclear decision

uranium mining in Sweden and breeder reactors than option two.

Having three options produces a situation fraught with difficulties. Although option three has been labelled the 'no' side, it is in fact advocating a further use of nuclear power — for 10 years. Options one and two have also labelled themselves 'phasing out' options, although they advocate a further use of nuclear power on a much larger scale than option three. The debate is not in fact about a 'yes' or a 'no' to nuclear power, but the number of reactor-years nuclear power should be allowed to stay. The public is not faced with a clear-cut choice. Another obvious difficulty with three options is how to interpret the results. The new government had a hard time appointing an Energy Minister, but they finally engaged the services of a non-party judge, Carl-Axel Petri. According to him, the support for options one and two will be counted together against option three. Option three must therefore poll more than the other two combined if it is to win. The leader of option three's campaign, Lennart Daléus, has said his option ought to be considered the winner if it polls more than either of the other two options singly. (The latest public opinion poll shows option one being supported by 25% of the population, option two by 34%, option three by 35%, with 6% undecided).

Although the referendum is advisory, all parties have said they will follow its result. But whatever the result, there will be political problems. It seems certain that options one and two will together poll more than option three. For Prime Minister Fälldin, opposition to nuclear power is a moral stance, and it is doubtful whether a referendum result could give him a moral absolute to preside over a government taking another six reactors into operation. In the unlikely event of option three's winning, there would be other political problems. The Centre and Communist

parties do not have a parliamentary majority and would therefore be unable to enact the measures the people had voted for. This would probably lead, sooner or later, to a government crisis and new elections.

While the different factions squabble, the Swedish Council for Planning and Coordination of Research is trying to produce impartial, informative material. It has engaged pairs of authors with different opinions on energy questions to argue their cases on eleven topics, including how to store nuclear waste, how to heat houses, nuclear power and nuclear weapons, and sun, wind and biomass. Each of the pairs has a mediator whose task it is to clarify where the authors agree and disagree.

Whatever the outcome of the referendum, the campaign has demonstrated a lot about the treatment of a complex scientific and technical issue in a democracy. Rational argument about energy has been relatively unimportant. What has been important is politics.

Supporters of option three oppose nuclear power largely, it seems, because they see it as a symbol of many unattractive features of modern, post-industrial life: individual isolation, large-scale technology, powerlessness of the individual to determine living conditions, and so on.

Supporters of options one and two talk about the waste of investment if the country does not use reactors it has built. What they envisage is essentially a continuation of Sweden's post-war history: an economically-expanding society using the latest technology to secure personal welfare. □

THE Swedes estimate that the International Nuclear Fuel Cycle Evaluation (INFCE) has increased their chances of obtaining United States approval for reprocessing spent fuel from their reactors. Because they use American enrichment facilities, they are currently forbidden to reprocess spent fuel under the US Nuclear Non-Proliferation Act of 1978.

After the INFCE discussions, however, the US may well give Sweden permission — however guarded — to send spent fuel to existing reprocessing plants and leave the plutonium there.

All Swedish decisions on nuclear matters are in abeyance at the moment, pending the referendum. Irrespective of the result, however, nuclear policy will probably develop along the lines of rejecting a national facility for reprocessing and not insisting on having the plutonium processed abroad sent back. Sweden might well sell its plutonium to the countries which reprocessed it. Such a development would dovetail nicely with some sort of American permission to reprocess.

The two countries are negotiating a new agreement on nuclear cooperation, and it will be as part of this agreement that the reprocessing question will be raised.

Drug innovation— what's slowing it down?

The research and introduction of new drugs has been slowing down in the UK and the US. At the same time, government regulations on the safety of new drugs have increased. But **Fred Steward** and **George Wibberley** argue that there is not a simple relationship between these two trends

THE INFLUENCE of government safety and efficacy regulations on pharmaceutical innovation has become a prominent issue in relations between the industry and the British government. Last April the Association of the British Pharmaceutical Industry (ABPI), in its "election manifesto", criticised the government for producing "a cumbersome and expensive regulatory edifice, much of which serves little useful purpose so far as the well-being of the public is concerned". Vice-President Dr Peter Main singled out as a fundamental concern "the effect that the ever-increasing delay caused by regulations relating to the testing of new products was having on pharmaceutical research and innovation". The Association's news sheet has continued to give emphasis to the issue, accompanied by headlines such as 'Murder by Regulation' and 'Take off the Cuffs'.

Last September the new UK Health Secretary, Mr Patrick Jenkin expressed his concern that controls for reasons of safety, quality and efficacy "can reach a point where they are so thorough, so pervasive and so foolproof that everything comes to a full stop". He was anxious that "unnecessary impediments to innovation should be removed".

These views on the drug industry have been accompanied by mounting pressure against government legislation by other sections of British industry, and they have been anticipated in many ways by apparently similar arguments in the United States. The recent federal review of industrial innovation attributed negative effects to laws concerning health, safety and the environment, a conclusion much in tune with President Carter's commitment to "reduce, rationalise and streamline the regulatory burden". Attention has been focused throughout the 1970s on the impact of such controls on the performance of the drug industry, culminating in the introduction of a variety of proposed drug regulatory reforms in

Congress during 1978 and 1979.

The time is therefore appropriate to ask what exactly are the effects of regulation on innovation in the drug industry? Two points need to be made at the outset: much of the data and analyses have looked primarily at the US situation; and there are factors other than the legal environment influencing drug innovation. The Pharmaceutical Innovation Group at Aston University has been gathering data on drug innovation in the UK with the aim of evaluating the influence of regulation compared to other factors.

The annual rate of introduction of brand-name pharmaceutical products which doctors in general practice can prescribe in the UK has declined substantially from 1960 to the mid-1970s (Fig 1). This includes duplicates, new formulations, dosages and combinations of existing drugs. New chemical entities (NCEs) — products containing a new chemical substance — comprise only a small proportion of all new products. The annual rate of introduction of NCEs into

Figure 1: pharmaceutical products introduced into the UK 1960-79

Fred Steward is lecturer in the Technology Policy Unit, and George Wibberley Professor of Medicinal Chemistry in the Department of Pharmacy at the University of Aston, Birmingham, UK. The authors collaborate in the Pharmaceutical Innovation Group at the university.

the UK market also declined in this period from about 30-40 to 15-20 per year; this rate remained reasonably steady throughout the 1970s.

Similar trends have been observed elsewhere. An analysis by Erika Reiss-Arndt of the annual rate of introduction of NCEs into the world market showed a decline, mainly in the late 1960s, from nearly 100 in 1963 to 65 in 1973. The rate of introduction of NCEs into the US market, according to the data of Paul de Haen, shows an even sharper drop, from over 70 in 1960 to less than 20 in the 1970s.

The general decline in the rate of introduction of new drugs in the 1960s coincided with the introduction of stricter requirements in the UK and the US for the pre-market testing of new drugs. In the US the 1962 Kefauver-Harris amendments asked for evidence of efficacy in addition to evidence of safety already needed under the 1938 Food, Drug and Cosmetic Act. In the UK, a system for evaluating drug safety was introduced after the thalidomide disaster. The non-statutory Committee on the Safety of Drugs chaired by Derrick Dunlop began operating in 1964 and was replaced by a statutory licensing system involving the Committee on the Safety of Medicines under the 1968 Medicines Act. This put emphasis on efficacy as well as safety.

There are two particular difficulties in assessing the relationship between these regulatory changes and shifts in the rate of innovation. The first is that the large size of the US market and the importance of the US industry means that domestic regulations affecting them may have wider international repercussions; and the second is the fundamental problem of separating the influence of regulatory and non-regulatory factors on the pattern of innovation.

If there is a need for government intervention to prevent the marketing of inadequate drugs, then as a consequence of established control mechanisms, a decline in the introduction of inadequate products would be expected.

The greatest decline in new drugs in the UK has been of those containing an active ingredient already available in some other product. In the past, the medical profession has criticised the proliferation of similar and unnecessary combination products. The Committee on the Review of Medicines recently emphasised their lack of therapeutic value. There have been few claims that innovation in the formulation of existing drugs has been inhibited in recent years. Instead, the decline in the introduction of products based on existing drugs appears to fulfil the explicit objectives of regulatory policy.

The fall in the rate of introduction of NCEs is more difficult to analyse. By definition they possess some chemical novelty, but this is no guarantee that they all offer benefits in terms of safety or effectiveness. In the US, the Office of

Figure 2: withdrawal of new chemical entities introduced in the UK 1960-75

Health Economics has obtained assessments by clinical experts of the therapeutic significance of NCEs introduced between 1958 and 1970.

Studying the introduction of NCEs in the UK, we found that the proportion in the bottom category of 'little or no advantage' dropped from 32% in 1960-63 to 18% in 1967-70. This included products which failed to meet the basic minimum standards set by the control system. Again, this decline appears to fulfil policy objectives. A classification by the Food and Drug Administration (FDA) of NCEs introduced in the US also showed a decline in the bottom category, representing 'no therapeutic gain', from 75% of 1961-1962 introductions to about 40% of introductions in the late 1960s and early 1970s.

It is remarkable that in the wide range of studies on regulation and innovation, relatively little effort has been devoted to exploring more thoroughly the degree to which the primary intended effects of regulatory change have been fulfilled. We have examined the rate of failure as shown by subsequent market withdrawal of NCEs introduced into the UK. The lack of attention given to this was illustrated early last year when the then Health Minister could not give any information in response to a parliamentary question about the extent of, or reasons for, the withdrawal of drugs from the UK market.

An NCE may be withdrawn for a number of reasons, including toxicity problems, inadequate efficacy and poor market performance. Our analysis of the withdrawal of NCEs introduced in the UK from 1960 to 1975 (Fig 2) shows a very much lower overall rate of withdrawal of NCEs introduced from 1964 onwards. Over 20% of the NCEs introduced in 1960-63, before the Committee on the Safety of Drugs started operation, were subsequently withdrawn from the market. Recent introductions may distort these

figures but the trend shown bears out the view that fewer drugs which ultimately failed reached the market after the establishment of stricter control.

The persistence of NCEs with unacceptable toxicity shows the importance of more effective surveillance of drugs when they enter medical practice. Some of the decline in the rate of introduction of NCEs in the UK therefore fulfils the goals of drug control policy.

The 1960s decline in the rate of NCE introduction, however, cannot be accounted for in this way. Increases in cost and length of time involved in discovering and marketing new drugs are also factors.

We measured the time from patent or publication, to the marketing of a new drug in the UK. Averaging about three years in the early 1960s, this rose to about 7.5 years in the early 1970s and remained then reasonably steady until a rise to nearly nine years in 1978-79. These increases have often been attributed to the demands of regulatory bodies, and it has been suggested that the overall decline in the rate of NCE introduction is a consequence of drug regulation.

But what are the other possible influences on the time and expense of drug research? A number can be suggested. The identification of many biologically important chemicals shortly after the war may have created a fruitful basis for innovation, for a period, but subsequently showed diminishing returns. Changes in the attention given to certain diseases could also have significant effects on the discovery and evaluation of new drugs. The complex aetiology of diseases such as cancer poses problems which cannot be resolved simply by expanding the screening of new compounds. The complexity of cardiovascular diseases again illustrates the difficulty of finding clear cut cures. There is, therefore, a need for more extensive evaluation of the effectiveness and toxicity of drugs intended for long-term administration.

Some of the areas in need of major innovation, such as inflammatory disease, raise the particular problem of suitable animal models for screening purposes. All these factors point to more complicated, time-consuming and expensive drug research. Another factor may be the rising expectation of researchers for more sophisticated and expensive equipment.

An analysis we have undertaken of the diseases for which new drugs are introduced in the UK shows a shift from infectious diseases in the mid-1960s to cardiovascular disease in the mid-1970s. Detailed information on pharmaceutical R&D in the UK is not readily available, but some figures have been published for the US by the Pharmaceutical Manufacturers Association. These show that in 1977 35.9% of total R&D expenditure was incurred by discovery-oriented work of synthesis, extraction, biological screening and pharmacological testing. Clinical

evaluation took 22.5%, toxicology and safety testing 9.2% and regulatory preparation and submission 3.3%.

Although the rate of introduction of NCEs stabilised during the 1970s, it is becoming harder to discover new molecules of real therapeutic importance. Of 83 NCEs approved by the FDA between 1974 and 1978, 62% were considered to offer moderate or important gains. This contrasts with only 33% of the 45 new molecules in pending new drug applications in March 1978.

Whatever the cause of increases in the cost and time of drug innovation, the consequence has been a decline in the "productivity" of R&D investment.

The influence of regulations in the US has received considerable attention, much of it concerned with different rates in the introduction of NCEs in other countries. William Wardell, in particular, has documented in detail a persistent "drug lag" in the US from 1963 onwards, shown by the high number of NCEs introduced in Britain but not marketed in the US, or only marketed there some years later.

Although the marketing strategy of a particular company determines the country in which the drug is introduced, many of the differences between the US and UK arise from differences in regulatory approach. There have been conflicts between the FDA and its critics over the therapeutic significance of the 'lag'. Some have argued that important new drugs such as sodium cromoglycate were excessively delayed while others have replied that the proliferation of very similar drugs, such as the non-steroidal anti-inflammatory drugs, has been avoided. Wardell has criticised the administration of the regulations and not the existence of the 1962 Amendments.

Perhaps an acknowledgement of all these points lies in the FDA's new fast-track approval process which allows important innovations to move more quickly through the regulatory system. The mean approval time for 'promising therapeutic advances' in the year beginning October 1978 was 19.4 months compared with an average of 39.2 months for those of 'little or no therapeutic gains'. But the speedier British system carries disadvantages. Of the four NCEs introduced in the UK since 1964 that were later withdrawn on the ground of unacceptable toxicity, three (ibunefac, practolol and alclofenac) were never introduced in the US.

Any comparison of the risks of adverse drug reactions with the risks of delay in the introduction of important new drugs, presents serious difficulties. The assumption that reduction in the risk of adverse effects from drugs must be accompanied by an increase in the time taken for their introduction is not necessarily valid. Labels for regulatory systems such as 'strict' or 'fast' should be used cautiously especially when comparing

one system with another.

The underlying weakness of many studies on the relationship between drug regulation and innovation is that they treat R&D as a "black box" and use highly aggregated measures of innovative output. Although correlations have been observed between factors such as regulatory change, development time, research costs, and the rate of innovation, they have not been accompanied by comprehensive explanations of what changes have been taking place within the research process.

The decline in R&D productivity has meant changes in strategy. The proportion of expenditure on "basic" as opposed to "applied" research in the US drug industry fell steadily over the decade 1968-78 from 15.4% to 11.4%. British data are not precise enough to detect such a trend. There also seems to have been a move away from less economically significant disease, such as those affecting small numbers of people, or those prevalent in poorer parts of the world. Our analysis of the introduction in the UK of drugs for uncommon illnesses as a proportion of all new drugs shows a drop from 7.1% in 1960 to 4.7% in 1971-76. These changes are taking place in the context of companies concentrating on fewer therapeutic areas. Jerome Schne

has shown that those US drug firms which concentrated research on fewer areas produced an average of 1.3 NCEs in 1972-75 while those which diversified their research generated an average of only 0.67.

These changes in R&D strategy may have major social consequences. The shift from basic research may well result in just the opposite effect to the closer relationship between basic and applied science. Changes in the therapeutic categories receiving attention may mean a neglect of important breakthroughs in less commercially attractive areas. Although such research decisions have widespread repercussions, they are not subject to any direct form of social control. The proposition that less, rather than more, government intervention is required in relation to drug innovation is at least an arguable one.

The precise relationship between regulation and innovation has yet to be established, and it is unlikely to be determined by further studies which attempt to quantify the adverse effect of regulation but do not examine the full range of factors which may influence drug innovation. We are exploring research and innovation in the drug industry with this perspective in mind. □

NEWS AND VIEWS

Neural tube defects: towards prevention and understanding

from Gill Morriss

ANENCEPHALY and spina bifida aperta are open neural tube defects (NTD) with an overall population frequency in Britain of 1 in 500 and 1 in 400 respectively, although there are marked geographical variations¹. Their aetiology is not well understood, so that prevention has, until now, been possible only through antenatal diagnosis (alpha-fetoprotein testing) and subsequent abortion.

In a recent clinical trial the expected incidence of NTD was greatly reduced after prospective mothers at high risk were given vitamin supplements before conception and during the early weeks of pregnancy. If these results hold up in more extensive tests, true prevention will become a possibility in many cases.

These results are also interesting scientifically as they indicate that environmental (in this case nutritional) factors may have a much greater weighting in an individual's predisposition to NTD than was formerly realised. It is therefore possible that relatedness to an affected individual increases predisposition to the same malformation through common environmental factors as well as through common genes. The interaction between environmental and genetic factors has also been highlighted in recent work on a mouse model for NTD.

Before discussing these reports in more detail, it is useful to consider the concept of predisposition to malformation as proposed by Carter¹. The combined environmental and genetic factors predisposing an individual to the risk of malformation during development ('individual' here refers to the embryo) are assumed to be normally distributed in the population for any specific congenital malformation. The threshold at which an individual's total liability will result in malformation, lies well away from the mean population level of predisposing factors. This distribution is indicated by the solid line in Fig. 1. There are subpopulations within the general population which have an increased risk. For example, an increased predisposition can be predicted for the relatives of an affected individual (the index patient). According to Carter's model, the risk will depend on the number of predisposing

genes they have in common with the patient: 50% for first degree relatives (siblings and offspring), 25% for second degree relatives (nephews and nieces) and 12.5% for third degree relatives (first cousins). Increased risk within a subpopulation is indicated in Fig. 1 as a shift of the distribution curve to the right, so that a larger number of individuals have above threshold levels of predisposing factors (broken line). (Fraser² has used a similar diagram to illustrate the shift in the normal distribution curve to the right when two teratogens interact additively: genetic/environmental interactions can also be depicted in this way.)

Evidence for the importance of genetic factors in the causation of NTD comes from family studies and from racial variations which are at least partially maintained after migration. Evidence for the importance of environmental factors comes from studies on the effects of social class, maternal age and birth order, seasonal variation and so on³. In reality, it is impossible to assess the relative importance of genetic and environmental factors, nor even to distinguish between them adequately. Families and close-knit communities tend to have many cultural factors in common and nutritional habits may be maintained after migration. The reasons for the marked geographical variation are similarly obscure. Even though the reasons for differences in predisposition are so poorly understood, the increased risk of recurrence within a family is well documented: for instance, in the South Wales study of Carter, David and Laurence⁴, 5.2% of siblings of an NTD index patient were themselves affected, compared with an incidence of 0.77% in the general population of that region. (The latter figure is itself high compared with other regions.)

It was on the basis of these studies that Smithells *et al.*⁵ were able to select a high-risk group of potential mothers to test the hypothesis that the social class gradient in incidence of NTD was due to nutritional factors. Their own earlier studies had indicated that red cell folic acid and leukocyte ascorbic acid (vitamin C) deficiencies in early pregnancy might be correlated with NTD⁶. 175 women who had previously given birth to an NTD infant, and who wished to become

Fig. 1 Shaded area represents malformed individuals (see text). Modified from Carter¹.

pregnant again, were included in the study. They were given a multivitamin and iron preparation for at least 28 days before conception, continuing at least until the date of the second missed period, that is beyond the normal time of neural tube closure, which is completed 25 days after conception. (In view of the earlier suggested correlations with folic and ascorbic acid deficiencies, it is unfortunate that such a blanket preparation was used.) Only one of these mothers has produced a further affected infant. Fifteen mothers had an even higher risk than the rest of the group by virtue of having had two previous NTD infants; none of these had a further affected child. (The figures include 26 continuing pregnancies with normal amniotic fluid alpha-fetoprotein levels.) The recurrence rate of 1 in 178 infants (3 twin pairs) could be slightly higher than the 0.6% calculated, since there were 10 unexamined spontaneous abortions. Nevertheless the result is encouraging when compared with the recurrence rate in the control group (no vitamin supplementation), which was the expected number, 13 of 260 infants (5.0%).

Caution is essential at this stage: it is salutary to recall that the suggestion that anencephaly and spina bifida were "usually preventable" by avoidance of blighted potatoes, was also supported by impressive statistics⁷. It is therefore very much to be hoped that the results of the nutritional supplementation study will be confirmed by extension of the trial to larger numbers of patients.

The concept of genetic and environmental factors affecting the teratogenic threshold has been highlighted recently in studies on the curly-tail mouse^{8,9}. This is a

Gill Morriss is a lecturer in the Department of Human Anatomy, University of Oxford.

mutant with an incidence of spina bifida, exencephaly (\equiv anencephaly) and related axial defects of around 50%. In outcrossing experiments with BALB/c and A strong random bred strains, the incidence of the curly-tail phenotype was reduced to 24% and 8% respectively (F_1 female backcrossed with curly-tail male parent), that is, the expression of the (recessive) gene was modified by the maternal genetic background.

The expression of exencephaly, unlike that of spina bifida, was strongly sex-linked, with an overall ratio of 0.25 male:female. A similar bias has been observed in another mouse mutant with a high incidence of exencephaly¹⁰, and the same has long been recognised in human anencephalics (ratio 0.34 in the South Wales study of Carter, David and Laurence⁴). These observations suggest that anencephaly involves a sex-linked gene-gene interaction, acting either on morphogenesis or on subsequent viability. Why this should be so for anencephaly and not for spina bifida is unclear, but it is apparent from morphological and ultrastructural observations that the sequence of mechanisms involved in morphogenesis of the cranial part of the neural tube is more complex than that of the spinal region¹¹. The striking morphological difference between the two regions is illustrated in a five-somite rat embryo in Fig. 2.

Excess vitamin A is well known as a teratogen which can affect neural tube closure when administered before or during the period of neurulation. Seller *et al.*⁹ have compared the effect of various dose levels of vitamin A given to curly-tail and A strong mice on day 8 of pregnancy. The effect of interaction of this environmental teratogen with the NTD-disposed curly-tail genotype was a shift of the teratogenic response to the right, that is, NTD resulted from lower dose levels in curly-tail compared with A strong mice. The higher dose levels, merely teratogenic in A strong, were lethal in curly-tail. This is a nice example of genetic/environmental interaction.

An intriguing result from another set of

Fig. 2 Scanning electron micrographs of 5-somite (left) and 9-somite rat embryos. At 5 somites the cranial neural folds are relatively large, convex structures compared with the V-shaped neural groove of the spinal region. By the 9-somite stage, when neural tube closure has begun in the cervical region, the shape of the neural folds is similar in both cranial and spinal regions.

experiments in this series was the observation that administration of the two lower dose levels of vitamin A (5 mg kg⁻¹ and 10 mg kg⁻¹) to curly-tail mice on day 9 resulted in a significant decrease in the proportion of malformed fetuses (33 and 36% respectively, compared with 54% in the sham-injected controls). This result is not to be compared with the effects of vitamin supplementation in high risk women — in the animal experiment we are considering a paradoxical genetic/environmental interaction, since administration of the same dose levels one day earlier had a potentiating effect on the genetic predisposition to NTD.

One must emphasise here that there are many possible interpretations of these observations, particularly since the neural tube of normal mice has completed closure by day 9, and it is usually assumed that open NTD are the result of failure of closure of the tube. Indeed, many previous studies on excess vitamin A have failed to induce defects following injection on day 9¹². It may be that NTD in the curly-tail mouse are associated with a propensity for delayed neurulation, and that vitamin A administered on day 9 interacts with the genetically-induced abnormal morphogenetic mechanisms in such a way as to increase the number of still open neural tubes which are able to complete closure at this late stage.

However, the possibility that there is secondary reopening of a closed tube cannot be altogether ruled out. At the region of closure (the dorsal midline) the closed neural tube and the surface ectoderm above it are both thin epithelia which are very easily broken during preparative procedures such as paraffin embedding, suggesting that a potential weakness may exist here in the living embryo. This said, it must be recognised that the weight of experimental evidence supports the assumption that open NTD usually result from failure of the neural tube to complete closure. This has been demonstrated in the case of excess vitamin A, for instance, by the addition of retinol

or retinoic acid to the culture medium in which neurulating rat embryos are developing¹³. Unfortunately vitamin A is of limited usefulness as a teratogen if one is searching for mechanisms at the cellular or molecular levels, because the molecular nature of its effects on morphogenesis is still obscure.

As one would expect in a system involving curvature of an epithelium, neural tube closure can be prevented by culturing embryos in the presence of substances such as cytochalasin B, which affect the contractile properties of actin-containing microfilaments¹⁴. But organised breakdown of microfilament bundles occurs in the most lateral cells of the neural epithelium in the last stage of curvature towards the midline before fusion during normal development; if this particular breakdown of microfilament bundles does not occur, neural tube closure again fails¹⁵. These contrasting observations illustrate the complexity of the process of neurulation, and make it clear that no single factor or group of factors can explain the cause and genesis of NTD.

Although the curly-tail mouse was first proposed as a model for human NTD twenty-one years ago¹⁶, no attempt has yet been made to investigate the morphogenetic basis of the observed abnormalities. The studies discussed above confirm the potential of this mutant, and demonstrate the interaction of genetic and environmental factors, but they do not provide any insight into the morphogenetic mechanisms underlying the NTD. Such insights will come only through painstaking observations of the embryos themselves, before and during the process of neurulation. Wilson and Finta¹⁷ have investigated the genesis of spina bifida in the splotch mouse mutant in this manner, and have found abnormally large numbers of gap junctional vesicles in the day 9 neural epithelium at the level which fails to form a closed tube. They discuss the possibility that these vesicles may be the visible result of an earlier process which has

interfered with normal cellular contact mechanisms such as intercellular communication or adhesion; this interpretation is supported by the observation that the neural epithelium subsequently develops a looser structural organisation

than normal¹⁸.

Morphogenetic patterns and mechanisms in postimplantation embryos present serious problems of analysis because of their enormous complexity. However, we must come to terms with

these difficulties if we are to improve our ability to interpret and predict causes and origins of human malformations, and to be able to extrapolate from the results of experimental work on laboratory animals to man. □

Speckle interferometry of Pluto

from David W. Hughes

THIRTY years ago Kuiper used the 200-inch Mount Palomar telescope and a 'disk meter' to measure the diameter of Pluto, the ninth planet of the Solar System. He found a value of about 5,900 km but was considerably worried by possible systematic errors. The disk meter produces an artificial image of variable angular diameter, brightness and colour. These quantities are then adjusted until the artificial image and the image of Pluto look similar. The angular diameter of the planet can then simply be read off. Times change and in March 1978 S. J. Arnold and A. Boksenberg of University College, London and W. L. W. Sargent of the California Institute of Technology used the same telescope and observed the same planet but this time with a speckle interferometer at the Cassegrain focus. The value obtained for the diameter was $3,600 \pm 400$ km, this value however depending on the assumption that the planet disk was limb darkened. Their results have been published in a recent edition of *The Astrophysical Journal* (234, L159; 1979).

Speckle interferometry is a fascinating technique which has been developed extensively in the past 10 years and has been used to measure the diameters of stars, the separation of binaries and to study fine structure on the Sun and on the surfaces of supergiant stars. Atmospheric turbulence distorts the plane radiation wavefront from the astronomical object, a wavefront which has travelled more or less undisturbed through space. This corrugation serves to make a single large telescope mirror act as a multitude of smaller ones with individual sizes of around 10 cm. Small erratic movements are produced in the image position and the overall image is blurred, distorted and considerably enlarged. Turbulence is the main limitation to the resolving power of the telescope and the resulting image can be up to 80 times larger than the diffraction-limited image (the so-called Airy disk).

The speckle interferometric technique relies on taking many short exposure pictures of the object. This freezes the effects of turbulence such that the 'speckles' that make up each individual image are in essence distortion free. Each image is analysed statistically, the end result being a nearly diffraction-limited

image of the original object. Arnold, Boksenberg and Sargent took 170,000 'pictures' of Pluto, each having a 20 millisecond exposure. Each picture was produced by an image photon counting system consisting of a 256×256 element array which could find electronically the centre of each photon event. The information was recorded onto digital magnetic tape. Observations were centred on a wavelength of 5,000 Å with a bandwidth of 350 Å. There were about three photon events in each picture and each picture element was roughly equivalent to an angular extent of 4×10^{-3} arc s on the sky.

The image of Pluto was compared with two stellar images, one being Alpha Herculis A which had a known diameter and the other GC24617 which should be unresolved. The authors found a systematic error of 0.035 ± 0.010 arc s in their results which they thought might be due to an incomplete compensation for atmospheric dispersion and to the possibility that the speckles were not completely stationary over a period of 20 ms.

They conclude that the best fit to the profiles would be obtained if the disk of Pluto subtended an angle of 0.17 ± 0.02 arc s at the telescope and was limb darkened. The presence of limb darkening was deduced by Renschen (*Astronomische Nachrichten* 298, 179; 1977) from observations of Pluto's light variation as a function of time. The authors assume that this limb darkening follows a simple cosine law rather like that of the solar limb darkening. Titan, the 2,440 km radius satellite of Saturn, is also limb darkened like this. Arnold, Boksenberg and Sargent also found marginal evidence for an asymmetry in their data suggesting the presence of Pluto's moon. Also the surface of Pluto seems to have a variable albedo — half of it being covered with high albedo (0.5) methane frost and the remainder being of albedo about 0.13.

Combining the results with other recent observations leads to the conclusion that Pluto has mean opposition visual magnitude of 15.12, Pluto's moon being about 10.8^m. The mass is $(1.9 \pm 0.3) \times 10^{-3}$ Earth masses, the diameter is $3,600 \pm 400$ km and the mean density $0.5 (+0.3, -0.2)$ g cm⁻³. The low value for the mean density suggests that Pluto is made up predominantly of frozen volatiles. The

authors are obviously not too convinced about their limb darkening assumption and they carefully quote another set of results for the non limb darkened case. The mass obviously stays the same but the diameter and density change to 3,000 km and $0.8 (+0.6, -0.3)$ g cm⁻³ respectively.

As time progresses Pluto is looking less and less like a planet and more and more like an escaped planetary satellite. □

Soil seed banks

from Peter D. Moore

As any gardener knows, the soil seems to be full of seeds of a variety of species, some needing only warmth and water to germinate and others whose dormancy is not so easily broken. Harper (*Population Biology of Plants*, Academic Press, 1977) likens these respectively to a current and deposit account in a bank and the term 'seedbank' is one that is frequently used for this latent plant community.

A striking feature of the seed bank is the general disparity between the species contained in it and the present-day vegetation. Many examples could be quoted, such as the work of Kellman (*Can. J. Bot.* 48, 1383; 1970) who found that 70% of the seeds which germinated from soils beneath a century-old *Pseudotsuga* and *Tsuga* forest in British Columbia were *Alnus rubra*, many of the remainder being weeds. The possibility that the seeds had come in from other areas could not be excluded, but it was also considered conceivable that the seed population belonged to an early successional stage following a fire which had taken place a hundred years before.

Besides the disparity between present-day vegetation and seed bank, the seed bank itself can be extremely heterogeneous throughout the site. Van der Valk and Davis (*Can. J. Bot.* 54, 1832; 1976) used a Sorensen similarity index to compare the viable seed flora of mud samples from fresh water marshes in Iowa. Within marshes their indices varied from 2 to 68% and between marshes (eight were studied), indices fell between 24 and 28%. They account for the variability in terms of the time over which any given seed bank has accumulated and the local variation in

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, King's College, London.

David Hughes is a lecturer in the Department of Physics, University of Sheffield.

vegetation history.

An exception to the vegetation/seed bank disparity has recently been described by Leck and Graveline (*Amer. J. Bot.* **66**, 1006; 1979) from the freshwater tidal marshes of the Delaware River estuary, New Jersey. These marshes contain a very diverse flora with annuals being particularly important; the tidal fluctuations render the habitat liable to regular disturbance by flooding. Annuals were common in the seed banks of these habitats, accounting for 7 out of the 10 most abundant species, and of the 10 most frequent species germinating, an average of 7.2 species were growing at the collection site.

This exception to the general rule may contain clues to the normal lack of correlation between vegetation and seed banks. The seed bank usually contains a high proportion of early successional (r-selected) species which rely on long-term viability as part of their opportunistic strategy. Late successional (K-selected) species gain no advantage from such persistence but must in consequence re-invasion sites by new propagules following disturbance.

This is an oversimplification of what is evidently a complex of interactions, and a more extensive and systematic analysis has now been formulated by Thomson and Grime (*J. Ecol.* **67**, 893; 1979). They divide seed banks into four types (I-IV) which are thought to differ in their ecological significance. The types are defined by the temporal pattern of germination under normal field conditions. In species of type I and II the seed bank is non-persistent and temporary, seeds germinating either in the autumn after their production, or the following spring. Such types are associated with habitats in which regular gaps are formed seasonally and re-invasion depends on predictable, seasonal factors. In species of type III and IV there exists an increasingly large, persistent seed bank, which confers advantages under conditions where disturbance, and therefore the opportunity for germination, is unpredictable and not closely linked to season. It is natural therefore, that studies of the persistent soil seed banks show a predominance of weed species of essentially type IV. Where successional mature vegetation now dominates such sites, the contemporary dominants are unlikely to be well represented in the soil seed assemblage, for they are likely to possess type I or II features. This will result in the disparity so often observed between vegetation and the local seed flora. The exception, described from the New Jersey tidal marshes, experiences such frequent (but unpredictable) disturbance that the current vegetation is largely composed of type IV seed bank species as of course, is the soil seed bank. The model, developed on the basis of grassland studies, seems robust and will undoubtedly be applied with profit to many other habitats. □

DNA sequence of human papovavirus BK

from Peter M. Howley

THE papovaviruses, including Simian virus 40 (SV40) and its murine counterpart polyoma (Py), are small DNA viruses which have been well studied as models in tumour virology and to elucidate the mechanisms of eukaryotic gene expression. These viruses are oncogenic when injected into hamsters and can malignantly transform some mammalian cells *in vitro*. The first human papovaviruses were isolated in 1971; BK virus from the urine of a renal allograft recipient on immunosuppressive therapy (Gardner *et al. Lancet* **i**, 1253; 1971), and JC virus from the brain of a patient with a rare demyelinating disease, progressive multifocal leukoencephalopathy (Padgett *et al. Lancet* **i**, 1257; 1971). As BK and JC are also oncogenic in newborn hamsters and can transform certain mammalian cells *in vitro*, they have attracted interest because of their potential role in human neoplasia.

Serological studies indicate that BK and JC are ubiquitous in the human population; seroconversion occurs usually in childhood and 70–80% of adults from widespread geographical areas have antibodies specific for each of these viruses. Since BK can be readily propagated in a variety of cultures of human fetal cells and JC grows well only in cultures of primary human fetal spongioblasts (Padgett *et al. Infect. Immun.* **15**, 656; 1977) and to a limited degree in cultures of primary human amnion cells (Takemoto *et al. J. Virol.* **30**, 384; 1979), the molecular studies of the human papovaviruses have been largely limited to BK. Subsequent isolations of BK have been made exclusively from patients undergoing immunosuppressive therapy or suffering from an underlying immunodeficiency. (The laboratory strains of BK currently used are listed in Table 1.) The potential role of BK in human malignancy has been examined by several laboratories

and although conflicting reports have appeared, there is little convincing evidence to associate BK with human cancer (Fiori & DiMayorca *Proc. natn. Acad. Sci. U.S.A.* **73**, 4662; 1976; Israel *et al. Virology* **90**, 187; 1978; Wold *et al. Proc. natn. Acad. Sci. U.S.A.* **75**, 454; 1978).

The structure and genetic organisation of the BK genome are similar to those of SV40 and polyoma. The viral genome is a 3.4×10^6 molecular weight double-stranded circular molecule, equally divided into 'early' and 'late' sets of genes (for a recent review of the molecular biology of BK see Howley in *Viral Oncology* (ed. Klein) 489, Raven Press, New York, 1980). The early region, transcribed before the onset of DNA replication, encodes at least two polypeptides, large T antigen (97K) and small t antigen (17K) (Simmons & Martin *Proc. natn. Acad. Sci. U.S.A.* **75**, 1131; 1978). Three structural proteins (VP1, VP2, and VP3) are translated from the late transcripts.

Recently two laboratories have independently determined the complete nucleotide sequence of three different strains of BK: the prototype BK, BK(Dun), and BK(MM) (Seif *et al. Cell* **18**, 963; 1979; Yang & Wu *Science* **206**, 456; 1979). Comparison of these BK DNA sequences with the SV40 DNA sequence (Reddy *et al. Science* **200**, 494; 1978; Fiers *et al. Nature* **273**, 113; 1978) has provided definitive confirmation of earlier DNA-DNA hybridisation studies which indicated extensive sequence homology between the SV40 and BK genomes (Newell *et al. J. Virol.* **25**, 193; 1978; Howley *et al. J. biol. Chem.* **254**, 4876; 1979). The genetic organisation of BK seems identical to that of SV40 and a comparison of the BK viral sequences with analogous regions of the SV40 genome permits the localisation of coding regions and regulatory functions

Table 1 Strains of BK virus

Virus	Source	Reference
BK (prototype)	Urine, renal allograft recipient	Gardner <i>et al. Lancet</i> i , 1253; 1971.
BK(MM)	Urine and brain tumour, Wiskott-Aldrich syndrome	Takemoto <i>et al. J.N.C.I.</i> 53 , 1205; 1974.
BK(Dun)	Urine, Wiskott-Aldrich syndrome	Howley <i>et al. J. Virol.</i> 16 , 959; 1975. Manaker <i>et al. Virology</i> 97 , 112; 1979.
BK(RF)	Urine, renal allograft recipient	Dougherty & Stefano, <i>Proc. Soc. exp. Biol. Med.</i> 146 , 481; 1974.
BK(MG)	Urine, renal allograft recipient	Lecatsas & Prozesky, <i>Arch. Virol.</i> 47 , 393; 1975.
BK(GS)	Urine, renal allograft recipient	Wright <i>et al. J. Virol.</i> 17 , 762; 1976.
BK(DW)	Urine, renal allograft recipient	Wright <i>et al. J. Virol.</i> 17 , 762; 1976.
BK(JM)	Urine, Wiskott-Aldrich syndrome	Howley <i>et al. J. Virol.</i> 16 , 959; 1975.
BK(JL)	Urine, bone marrow allograft recipient	Pauw & Choufoer, <i>Arch. Virol.</i> 57 , 35; 1978.

for both lytic growth and transformation.

There are two regions where differences exist among the three strains of BK sequenced. The first is located in the non-coding tandem repetitive sequences to the late side of the origin of DNA replication. There is a 42 base pair deletion in the BK(Dun) genome compared with the prototype BK sequence. The BK(MM) genome varies more markedly from the other two DNAs in both the sizes and the patterns of these repeated sequences. Tandem repetitive segments are located in the corresponding region of the SV40 genome although they bear no sequence homology to the repeats of BK DNA. Variation also occurs in these tandem repetitive segments among different strains of SV40 and portions of these repetitive segments can be deleted without any apparent effect on the biological function of the virus. Thus there is apparently little sequence constraint in this region among papovaviruses generally or even among strains of the same virus, and its biological function and significance remain obscure.

Differences were also noted in the early region of the genomes of the BK strains. Although the sequences of the early regions of the prototype BK and BK(Dun) are identical, there is a deletion of 262 base pairs in the BK(MM) early region. This deletion removes sequences from the putative intervening sequence for large T antigen, including the likely donor site for the small t antigen splice junction. As a consequence, BK(MM) does not encode a small t antigen (Seif *et al. Cell* **18**, 963; 1979) making it equivalent to some of the constructed early viable deletion mutants of SV40 which map in the analogous region of the SV40 genome. Since BK(MM) can replicate in tissue culture and can induce tumors *in vivo* as well as transform cells *in vitro*, the small t antigen must be dispensable for these functions of BK.

While remarkable similarities can also be found between the genome of BK (or SV40) and that of polyoma, significant differences exist (Soeda *et al. Nature* **283**, 445; 1980). The BK and SV40 genomes contain a large non-coding region between the carboxy terminal ends of large T antigen and VP1 (approximately 100 base pairs), whereas the same region in polyoma contains only seven base pairs. In addition the polyoma genome does not contain the region of tandem repetitive segments in the non-coding region to the late side of the origin of DNA replication as do BK and SV40. The late leader regions of each of the BK and SV40 genomes contain an open reading frame following an initiator AUG referred to as the 'agnogene'. Although proteins encoded by these sequences have not yet been detected, approximately 2/3 of the putative amino acids are conserved

Testing gravitational theories

from Bruno Bertotti

DURING their mission to Mars in 1976 and 77 the four Viking spacecraft verified Einstein's predictions concerning the additional delay in the propagation of an electromagnetic signal due to the gravitational field of the Sun with an accuracy of 2×10^{-6} , much better than any previous determination. A recent letter to the *Astrophysical Journal* (**234**, L219; 1979) by R.D. Reasenberg and others has now made public the details of this outstanding experimental achievement. This additional delay has the largest value, 250 μ s, when the signal grazes the Sun; with the Viking spacecraft (two orbiters and two landers) it was possible to measure corrections of 50 ns, corresponding to distances of 7.5 m. The main technical reason for this large precision was that the signals came from a lander, firmly anchored to the surface of the planet, whose motion is very regular and predictable.

This is another example of the extraordinary accuracy to which space research has pushed our knowledge of the geometry of the Solar System and, consequently, of such dynamical properties as the planetary masses; and there is still scope for improvement, mainly through the implementation of better telecommunication systems at higher frequencies (including the use of laser signals).

In my view this experiment marks also the end of one phase in gravitational research, which aimed at testing all the

theories of gravitation which are based on the assumption that space-time has a metric structure (described by its curvature) and that the Principle of Equivalence — all local laws have a universal validity — holds. These assumptions have been precisely formulated in a mathematical scheme, which has also led to the classification and the experimental consequences of all possible theories of this kind (see for example, Will, in *Experimental Gravitation* (Ed. Bertotti) Academic Press, New York, 1973). In recent years all these theories have been to a large extent falsified by experiment and theoretical arguments, except general relativity, whose predictions have all been confirmed to a greater and greater accuracy.

It seems, therefore, that the experimental programs within this theoretical framework have passed the point of diminishing returns. This does not mean, however, that in the physics of gravitation there are no open questions and potential anomalies. Perhaps the most important one is the possible change of the constant of gravitation G over a cosmological time scale, which has been extensively studied by P. Dirac and V. Canuto. If this is true, not only is Einstein's theory violated, but the whole of astrophysics and cosmology must undergo a drastic revolution. The tests of the constancy of G are not yet sufficiently precise to exclude this possibility; and precise geometrical measurements in the Solar System, especially if extended over a long period of time, will probably be crucial.

between the BK and SV40 genome suggesting perhaps, that a protein exists. No corresponding 'agnogene' is present in the late leader region of polyoma.

The most significant difference between the DNAs of BK (or SV40) and Py lies in the genetic organisation of the early regions and possibly reflects the different host ranges of these viruses. The BK and SV40 early regions are extensively homologous throughout and each encodes only two known major early proteins, large T and small t antigens. The Py early region encodes a third early protein, middle T antigen (Ito *et al. Proc. natn. Acad. Sci. U.S.A.* **74**, 4666; 1977; Hunter *et al. Proc. natn. Acad. Sci. U.S.A.* **75**, 5917; 1978). Whereas the amino acid sequence of the Py small t antigen is remarkably similar to those of BK and SV40, the predicted Py large T antigen differs in two regions significantly from those of BK and SV40. First there is a 130 amino acid segment ('insertion') unique to the Py large T antigen located 100 nucleotides after the

early acceptor splice junction which has no counterpart in BK or SV40. The second difference is the carboxy terminus of the BK and SV40 large T antigens which is essentially absent from the Py large T. Interestingly the segment of DNA encoding this unique carboxy terminal portion in the BK and SV40 genomes is open in a second reading frame for approximately 300 nucleotides providing an additional potential coding segment. Putative peptides encoded by this segment of BK and SV40 would be hydrophobic and might thereby be used in associating a protein with a membrane; however, such peptides have not yet been demonstrated.

More light on membrane protein mobility

from Michael T. Flanagan

ONE of the most useful and unambiguous techniques for measuring the mobility of proteins in a membrane is fluorescence recovery after photobleaching (FRAP). In this technique, a cell is labelled as specifically as possible by saturating a membrane-localised receptor with its ligand which has previously been labelled with a fluorescent dye. As described in the original papers, a small circular spot ($\sim 8 \mu\text{m}$ in diameter) is bleached on the surface of the cell by exposing it to a focused laser beam of the appropriate wavelength to be absorbed by and destroy the fluorescent dye. The appearance of fluorescence within the circle after bleaching can arise only from the diffusion of unbleached material into the spot. The rate of this recovery is related in a relatively simple manner to the diffusion constant of the labelled molecular complex (Edidin *et al. Science* **191**, 466; 1976; Schlessinger *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 2409; 1976). The essentials of the method were first described by Poo and Cone (*Nature* **247**, 438; 1974) who, in the absence of laser technology, measured the diffusion constant of rhodopsin in amphibian disk membranes using the easily bleached natural chromophore, retinal. They found a value approximately one order of magnitude less than that found, by resonance techniques, to characterise the lipids of natural membranes. The difference between protein and lipid mobility has emerged as the most interesting theme linking the various FRAP experiments.

A difference might be expected simply because the proteins are much larger than the lipids. However, the first FRAP experiments carried out on mitogens and antibodies bound to cell membrane receptors, for example, concanavalin A on myoblasts, IgE on mast cells, demonstrated that the mobilities of these protein receptor complexes were determined by more than their size. In general two populations of complex were found; one immobile and one with a diffusion constant up to two orders of magnitude lower than that of the membrane lipid. The diffusion constant of the latter population fell dramatically in the presence of cytochalasin B. This microbial metabolite does not alter the mobility of the membrane lipids. As it is known to combine with elements of the cytoskeleton these FRAP results strengthened the growing belief that there is a physical link between some membrane receptors and the cytoskeletal structure underlying the membrane. FRAP has also been used to study lipid mobility in its own right and such studies have given additional

confidence in the validity of the technique. The diffusion constants obtained using small fluorescent lipid probes confirmed the values obtained from magnetic resonance studies (Wu *et al. Biochemistry* **16**, 3939; 1977). This study also illustrated the limitations of the technique. Diffusion constants in liquid crystalline phases of pure lipids, for example, in dimyristoylphosphatidylcholine above 23°C , could be measured but not those in the gel phase, that lipid below 23°C . To extend the detection limit of the technique to cover these high viscosity membranes Smith and McConnell (*Proc. natn. Acad. Sci. U.S.A.* **75**, 2759; 1979) introduced a very elegant modification to the technique that has, in addition, assumed considerable importance in examining possible interactions between receptors and cytoskeleton.

Instead of bleaching a spot Smith and McConnell bleached a series of parallel lines by first passing the laser beam through a ruled grating. A square wave pattern is produced which rapidly forms a sine wave pattern. The diffusion constant is obtained from the decay constant of the amplitude of the sine wave. Not only is the sensitivity improved but gross cellular movements can be compensated for as the frequency of the discrete pattern is not altered by protein-receptor complex or labelled lipid diffusion. McConnell's group have now examined the mobility of the M13 phage coat protein incorporated into an artificial membrane at temperatures both above and below the phase transition temperature of the lipid. The results in the gel phase were compatible with either protein aggregation or phase separation into protein-rich and protein-poor domains. In the liquid-crystalline phase a diffusion constant for the protein comparable with that of the lipid was found (*Biochemistry* **18**, 2256; 1979).

In their next modification to the FRAP method McConnell's group returned to the problem of protein mobility in natural membranes. They have shown that it is possible to measure the anisotropy of diffusion in a membrane by bleaching a two dimensional periodic grid pattern (*Proc. natn. Acad. Sci. U.S.A.* **76**, 5641; 1979). The reduction of the data is no longer simple and requires Fourier image analysis. By aligning one axis of the bleached grid pattern with the predominant direction of the 'stress' fibres of mouse embryo fibroblasts showing anisotropic arrangements in their cytoskeletal components they were able to obtain the diffusion constants of the succinylated concanavalin A receptor complex in the directions both parallel and perpendicular to the 'stress' fibres. These differed by up to a factor of 10; the parallel motion being the faster. The presence of a physical link between this complex and the

cytoskeleton now seems certain. Whether it is a direct anchoring link or a more subtle one involving exclusion of the complex from certain regions of the membrane cannot be determined by this technique alone but FRAP clearly will be a powerful tool in the study of the fate of such complexes.

The factors that determine protein mobility in a complex membrane, even in the absence of cytoskeletal interactions, are not fully understood. This is in part because the structure and dynamics of the mixed lipid membranes themselves are not totally clear. But it is also impossible to predict with certainty how a protein will behave in a hypothetical continuous homogeneous two-dimensional fluid. The equations describing diffusion in three dimensions possess neat analytical solutions; when constrained to two dimensions they do not.

Saffman and Delbrück (*Proc. natn. Acad. Sci. U.S.A.* **72**, 3111; 1975) have examined the consequences of this paradox in the context of protein diffusion in a biological membrane. The availability of methods for the accurate determination of both lateral and rotational diffusion constants (correlation spectroscopy for the latter) should now allow the theoretical model derived by these authors to be tested and several of the groups using the FRAP technique see this as one of their goals. Experiments are also being devised to examine the effect of the multicomponent nature of the lipid membrane on protein diffusion. Vaz *et al.* (*Proc. natn. Acad. Sci. U.S.A.* **76**, 5645; 1979) have taken the apolipoprotein, ApoC-III, as a model of a membrane protein and examined the effect of adding cholesterol to phosphatidylcholine bilayers on the mobility of the protein when bound to such bilayers. They believe that the protein is bound in the head group region of the membrane and that its mobility represents the upper bound for those values that will be found to characterise the integral membrane proteins.

Given the advanced state of the art of membrane reconstitution FRAP studies of several integral proteins are now feasible. In one of the first of these Schindler, Osborn and Koppel (*Nature* **283**, 346; 1980) measured the diffusion constants of the phospholipid, lipopolysaccharide and matrix protein in a reconstituted *Escherichia coli* outer membrane. They cannot reconcile their results with the model of Saffman and Delbrück and suggest that macromolecular diffusion in a membrane is more analogous to non-electrolyte diffusion through a polymer network than through a homogeneous fluid. FRAP experiments carried out on reconstituted systems containing enzymes whose activity has been shown to depend on the state or nature of the surrounding lipid, for example the ATP-dependent Ca^{2+} -transporting protein of the sarcoplasmic reticulum, will be of especial interest. □

REVIEW ARTICLE

Highly excited atoms

Harold J. Metcalf

Department of Physics, State University of New York, Stony Brook, New York 11794

Highly excited atoms are oversize, fragile species currently studied for both intrinsic interest and as detectors of IR and microwave radiation. Traditional quantum mechanics provides accurate descriptions of atoms in these exotic states and modern dye lasers are responsible for the new capability in their spectroscopy.

DURING the past four or five years the spectroscopy of very highly excited states of atoms and molecules has advanced dramatically. These atoms are especially interesting because the active electron is much less perturbed by the other electrons in the atom than when it is in lower states, and the atom is much closer to the ideal hydrogen-like model so frequently used. Such highly excited atoms are very rare in nature because of their large size and fragility, but they are found in interstellar space (H I regions). The primary reason for the increase in the laboratory study of atoms in these exotic configurations is the recent availability of tuneable dye lasers which can provide beams of very high spectral density over the entire optical spectrum^{1,2}. These laser beams can be easily directed into high vacuum regions where atoms are relatively free of perturbing interactions, and can be tuned to excite the atoms to specific highly excited levels of interest.

Although series of atomic levels have been studied for nearly 100 years (Balmer described the regularity of the visible lines of hydrogen in 1884), most spectroscopy experiments have been restricted to the few lowest lying levels, particularly those accessible by electric dipole transitions from the ground state. Tuneable lasers allow direct excitation to high levels, permit stepwise excitation by two sequential electric dipole transitions to states not directly accessible from the ground state, and can induce second-order processes such as two quantum excitation to otherwise inaccessible levels. With proper choice of laser frequency, intensity, and suitable applied external fields, one may selectively populate almost any excited atomic state. Atoms in highly excited states are called Rydberg atoms.

In the following description of Rydberg atoms we shall use atomic units, (AU). Energy is measured in units of twice the Rydberg constant ($\cong 2.2 \times 10^{-5} \text{ cm}^{-1}$), charge and mass in units of the electron's charge and mass ($e = 1$ and $m = 1$), and time in units such that \hbar also equals unity. Table 1 shows some common quantities measured in these convenient and ubiquitous units.

Table 1 Atomic units

$e = \hbar = m = 1 = \alpha c$
Unit of distance = $a_0 = \hbar^2/me^2 = 5.3 \times 10^{-9} \text{ cm}$
Unit of velocity = $ac = e^2/\hbar = 2.2 \times 10^8 \text{ cm s}^{-1}$
Unit of time = $\hbar^3/me^4 = 2.4 \times 10^{-17} \text{ s}$
Unit of energy = $2R = mc^2\alpha^2 = 2.2 \times 10^5 \text{ cm}^{-1} \times hc$
Unit of E field = $e/a_0^2 = 5.1 \times 10^9 \text{ V cm}^{-1}$
Unit of B field = $c/\alpha = 2 \times 10^9 \text{ G}$

Atomic structure, Bohr model

Many properties of Rydberg atoms can be understood correctly in terms of the relatively simple notions used to describe hydrogen atoms. For example, the deBroglie hypothesis that an integral number of electron waves must fit on the circumference of a classical orbit gives the same formula for the energy levels derived many years earlier by Bohr, and this formula gives a very

good approximation to the energy levels of Rydberg atoms. We have $E_n = -(mc^2/2)(\alpha Z/n)^2$ which becomes

$$E_n = -1/2n^2 \text{ AU} \quad (1)$$

for $Z = 1$. The energies are negative and approach each other and zero at larger values of n , the principal quantum number. The energy separation between adjacent levels is approximately $\Delta E = 1/n^3$ and Fig. 1 shows the Bohr energy levels given by this formula. (Contrast these energies with the energies $E_n \cong E_0 n^2$ of a particle bound in a square well, where the energy levels spread further apart with increasing n and there are a finite number of bound states.)

In the Bohr model, the speed of the electron is $\alpha c/n$ which becomes $1/n \text{ AU}$, and the radius of the orbit is $(n\hbar)^2/me^2$ which becomes just $r = n^2 \text{ AU}$. The picture that emerges of a Rydberg atom is one of an ion core and an isolated electron very far away, floating lazily around in a slow orbit, much like a distant planet of the Solar System. For $n = 100$ the orbit is as large as a living cell and the electron speed is only $2 \times 10^4 \text{ m s}^{-1}$.

Although the Bohr energy formula gives very good values for the hydrogen atom, it does not do as well as for other atoms because the valence electron's orbit may take it inside the closed-shell core where the potential descends very much more steeply than that of hydrogen. The electron therefore has much lower energy as shown by the s-levels in the central part of Fig. 1. The low angular momentum states (penetrating orbits) of alkali metals are therefore much more tightly bound than either the high angular momentum states (non-penetrating orbits) which see a nearly Coulombic potential or the corresponding n states of hydrogen. The differences between the high angular momentum states of alkalis and those of hydrogen arise because the ion core is composed of mobile electrons whose orbits can be perturbed by the valence electron. In the language of classical electromagnetic theory, we say that the core is polarisable and that its polarisability influences the energy of the high angular momentum states³.

Although departure of alkali energy levels from those of hydrogen arises from two rather distinct mechanisms depending on the angular momentum of the alkali state, the energy levels E_n of all the alkali levels are given very accurately by a single, empirically determined, minor modification to the Bohr formula:

$$E_n = -\frac{1}{2(n-\delta_l)^2} \cong -\frac{1}{2n^2} \quad (2)$$

Here δ_l is the quantum defect for a particular angular momentum l and a particular atom, and is nearly independent of n . Some representative values are given in Table 2. We expand equation (2) for the case $n \gg \delta$ and find

$$E_n \cong -\frac{1}{2n^2} - \frac{\delta}{n^3} = -\frac{1}{2n^2} \left(1 + \frac{2\delta}{n}\right) \quad (3)$$

for the energies of the alkali energy levels which agrees very well with spectroscopic data.

Fig. 1 Energy levels for various quantum mechanical systems. The left edge is a square well, the centre is the hydrogen atom, and the right half is the sodium atom.

Quantum mechanical discussion —no external fields

The quantum mechanical description of alkali atoms in Rydberg states begins with the Schrödinger equation for one electron in a Coulomb field, treating other effects such as spin orbit interaction (which decreases as $1/n^3$) as perturbations. The Schrödinger equation for hydrogen separates into a radial and angular part and the total wave function is the product $R_{nl}(r)Y_{lm}(\theta, \phi)$. The radial functions $R_{nl}(r)$ are the product of a Laguerre polynomial and a decreasing exponential in r . There are $(2l+1)Y_{lm}$ s that are solutions for each value of $l < n$ and that all have the same energy. Relativistic and radiative corrections produce the usual fine structure of these energy levels (spin-orbit splitting, Lamb shift, and so on) lifting the degeneracy among the states of different l and J . On the other hand, the effects of core polarisability and core penetration produces an electrostatic fine structure which also shifts the energy of states of different l , and these shifts are usually much larger than the relativistic ones. In fact, the spin-orbit splitting and Lamb shift are usually neglected in Rydberg spectroscopy because they are much smaller than other energy shifts (such as those arising from stray electric fields).

The quantum mechanical treatment^{3,4} of the perturbations on the valence electron in a high angular momentum state of an alkali atom begins with a derivation of the Hamiltonian term which arises from its interaction with the core. The electron polarises the core and the dipole thus induced acts back on the electron. An electron located at $r \gg r_{\text{core}}$ produces an electric field proportional to $1/r^2$ at the core, and the induced dipole moment produces an electric field at r proportional to $1/r^3$. Therefore, the additional field seen by the electron varies as $1/r^5$ and the potential of that field is proportional to $1/r^4$. We write

$$V_{\text{dipole}} = \frac{\beta}{2r^4} \quad (4)$$

where β (AU) is the classical polarisability and is of the order of unity (see Table 2).

We consider this potential as a perturbation to the Coulomb potential, evaluate its expectation values using the unperturbed wave functions of the hydrogen atom in the spirit of first-order perturbation theory (diagonal terms only), and find an energy shift

$$\begin{aligned} \Delta E_{\text{dipole}} &= \langle R_{nl}(r) | \frac{\beta}{2r^4} | R_{nl}(r) \rangle \\ &= \frac{\beta(3n^2 - l(l+1))}{4n^5(l+3/2)(l+1)(l+1/2)l(l-1/2)} \end{aligned} \quad (5)$$

For $l \sim n \gg 1$, $\Delta E_{\text{dipole}} \sim 1/n^8$ which is an extremely small correction to the energies. On the other hand, for fixed values of $l \ll n$ this term varies approximately as $1/n^3$, and the approximation is really very good. This is precisely the energy dependence needed to make the quantum defect formula equation (3) work, and shows why that formula can be very accurate for energies associated with induced dipole moments of the core. Of course, equation (5) is not valid for $l=0$, but the energy shifts for s states (penetrating orbits) are dominated by the increased Coulomb energy and not by core polarisability.

The energy arising from the induced dipole moment is the largest contributor to the shift of alkali energies away from the hydrogen energies (for non-penetrating orbits), but there are other sources of energy shifts. For example, the electric field at the core from the valence electron is not uniform (it depends on $1/r^2$) and the response of the core to either a uniform or non-uniform field may not be linear. Therefore the induced charge distribution need not correspond to a pure dipole moment, but may have quadrupole, octopole, and higher order terms. For each of these there is an addition to the Hamiltonian which can be treated similarly to the dipole term. It is a very curious property of the hydrogen radial wave functions that, for all potentials, V , that vary as an inverse integer power of $r > 1$, the leading term for the energy shift is proportional to $1/n^3$ (ref. 5). The result is that the quantum defect formula of equation (3) provides a very accurate prediction for the energy levels from interactions of different types (penetration as well as polarisation) because multipole terms are all proportional to some inverse powers of r . Finally, neither the electron nor the core is at rest resulting in various dynamic contributions to the polarisability (see discussion in ref. 4).

Equations (3) and (5) can be used to find approximate values for the quantum defects of non-penetrating states:

$$\delta_l \approx 3\beta/4l^5 \quad (6)$$

and the $1/l^5$ dependence is consistent with spectroscopic data as exhibited by the entries in Table 2. We can therefore use the tables of spectral data to determine the dipole polarisabilities of the ion cores. The deviations from a perfect fit to equation (6) (or the unapproximated results of equation (5)) can be used to determine the quadrupole polarisability or other higher order effects (such as dynamic effects, and retardation). Furthermore,

Table 2 The core polarisabilities and quantum defects for several of the alkalis*

	Core polarisability (AU)	Quantum defect			
		s $l=0$	p 1	d 2	f 3
Lithium	0.19	0.4	0.05	0.002	—
Sodium	1.0	1.35	0.85	0.014	0.0015
Potassium	5.5	2.18	1.71	0.27	0.010

Caesium	14	4.06	3.58	2.47	0.033

*For more detailed information see ref. 9.

high resolution studies of Rydberg atoms with particularly simple cores (helium, lithium) can provide a basis for comparison between atomic theory and experiment.

Rydberg atoms in external fields

The description of Rydberg atoms in weak external fields is very similar to that of ground state atoms, but the field strengths that can be called weak are very restricted. As highly excited electrons are weakly bound, moderate external fields can have large effects on them.

Consider first a semi-classical description of the effects of a magnetic field. For very small fields the atoms exhibit the usual Zeeman effect. But larger fields induce considerable diamagnetism in Rydberg atoms as a result of their large size: their orbital magnetic moments $M = ia$ (a = area) scale as $(1/n)$ ($n^4 = n^3$ and the interaction is quite large).

A complete quantum mechanical discussion of diamagnetism in Rydberg atoms is beyond the scope of this review and some unsolved problems are now attracting considerable attention. An outline of some first steps will be presented here. Note that the Hamiltonian for an electron in a field is (in AU)

$$\mathcal{H} = \frac{1}{2}(\mathbf{p} - \mathbf{A})^2 + V \quad (7)$$

where \mathbf{A} is the vector potential and V is the scalar potential of the electrostatic binding field. For $\mathbf{A} = 0$ the equation is separable; for a uniform magnetic field \mathbf{B} , $\mathbf{A} = \frac{1}{2}\mathbf{B} \times \mathbf{R}$. The $\mathbf{A} = 0$ solutions in spherical coordinates are also eigenfunctions of $\mathbf{A} \cdot \mathbf{p}$, the cross terms in the square in equation (7), and give the usual Zeeman effect. Although the A^2 term is negligibly small in ground state atoms, its r^2 (or n^4) dependence makes it significant for Rydberg atoms. When it cannot be neglected, the Hamiltonian is not separable in any coordinate system and a perturbation treatment is necessary.

We choose the basis set found from the solution of the separable Hamiltonian and evaluate the corrections to the energies from the Hamiltonian matrix elements. The first order diamagnetic shift⁶, found from equation (7), is

$$\Delta E_{\text{dm}}^{(1)} = \langle \psi | \mathcal{H}_{\text{dm}} | \psi \rangle = \langle \psi | (\alpha^2/8) B^2 r^2 \sin^2 \theta | \psi \rangle \quad (8)$$

where r and θ are the usual spherical coordinates and $\psi = R_{nl}(r)Y_{lm}(\theta, \phi)$ is the solution to the separated Schrödinger equation. To evaluate the angular part of this expression we use $\sin^2 \theta = (\text{constant}) Y_{2+2} e^{+2i\phi}$ and the properties of integrals of products of spherical harmonics. The radial part can be calculated from the Laguerre polynomials and the final result is

$$\Delta E_{\text{dm}}^{(1)} = \frac{\alpha^2 B^2}{8} \frac{n^2 [5n^2 + 1 - 3l(l+1)] (l^2 + l - 1 + m_l^2)}{(2l-1)(2l+3)} \text{ AU} \quad (9)$$

For $n \gg l \sim 1$, this becomes ($m_l = 0$)

$$\Delta E_{\text{dm}}^{(1)} \cong \frac{\alpha^2 B^2}{8} n^4 \text{ AU} = 5 \times 10^{-7} B^2 n^4 \text{ cm}^{-1} (B \text{ in Tesla}) \quad (10)$$

Observe that, for $n \approx 32$, the diamagnetic energy is comparable to the Zeeman energy (typically 1.4 MHz G^{-1}) at $B = 2 \times 10^{-5} \text{ AU} = 1 \text{ T}$. Also, the ratio of the diamagnetic shift to the Coulomb energy interval scales as n^7 so that these become comparable for $n \approx 42$ in the same field.

More accurate calculations of diamagnetic energy shifts require the off-diagonal matrix elements of the A^2 part of the Hamiltonian. It is clear from the $\sin^2 \theta$ dependence that the only non-vanishing angular integrals are those for which $\Delta l = \pm 2, 0$: A^2 can only connect states of the same parity and must satisfy a 'triangle condition' on the l values. It is also clear that $\Delta m = 0$ and that there is no selection rule on n . For strong fields and/or large values of n , perturbative calculations are not satisfactory and other methods of calculations are being explored.

Next we consider a semi-classical description of the effects of an electric field. Note that, even for very weak fields, there are

Fig. 2 The potential at the right results from adding the potential of a uniform field to that of the Coulomb field. E_c is indicated as the point where the electron is no longer bound to the force centre.

no perfectly bound states because there is always a finite distance from the atom where the electrical potential will be lower than the electron's binding energy. We therefore expect all expansions in powers of the field to diverge eventually. As an electric field acts on an atom through its induced dipole moment (which scales as r or n^2), and because the interaction is proportional to r , we expect energy shifts that scale as r^2 or n^4 and that can become quite significant in Rydberg atoms.

We begin a quantum mechanical description of Rydberg atoms in electric fields by noting that the Schrödinger equation can be separated in parabolic coordinates as well as the more common spherical coordinates even in the presence of a z -directed electric field⁷.

In contrast to the weak magnetic field case where the zero field eigenfunctions are also eigenfunctions of $\mathbf{p} \cdot \mathbf{A}$, the resulting radial differential equation for an electric field is not exactly soluble. Nevertheless, having the angular part separated makes the energy and eigenfunction calculations much easier. Parabolic coordinates are defined by

$$\begin{aligned} \zeta &= r + z = r(1 + \cos \theta) \\ \eta &= r - z = r(1 - \cos \theta) \\ \phi &= \phi \end{aligned} \quad (11)$$

We can write the solutions to the zero field Schrödinger equation as

$$u(\zeta, \eta, \phi) = u_1(\zeta)u_2(\eta)\Phi(\phi) \quad (12a)$$

where $\Phi(\phi) = e^{im\phi}$ as before and the energies of the levels are

$$E_n = -\frac{1}{2n^2} \text{ AU}, \quad n = n_1 + n_2 + |m| + 1 \quad (12b)$$

where n_1 and n_2 are the quantum numbers associated with the solutions for $u_1(\zeta)$ and $u_2(\eta)$.

In the presence of an electric field F the perturbation Hamiltonian is Fz (in AU) and we note that the matrix of Fz is diagonal in m because z commutes with L_z . In general the first-order perturbation correction to the energies is zero because Fz is an odd operator and has no diagonal matrix elements. However, hydrogen has some degeneracies between states of opposite parity which result in eigenfunctions of no definite parity, thereby producing finite diagonal elements. The first-order energy shift is then

$$\Delta E_s^{(1)} = \langle \psi | Fz | \psi \rangle = \frac{3}{2} \frac{Fn}{Z} (n_1 - n_2) \quad (13)$$

which scales as n^2 . In the more general case where there is no degeneracy, one must use the off-diagonal matrix elements and

Fig. 3 A typical apparatus showing the major components.

second-order perturbation theory to find

$$\Delta E_s^{(2)} = -\frac{F^2}{16} \left(\frac{n}{Z}\right)^4 [17n^2 - 3(n_1 - n_2)^2 - 9m^2 + 19] \quad (14)$$

which scales as n^6 . The ratio of the second order Stark shift to the Coulomb energy intervals scales as n^9 and becomes unity for $F = 10^{-6} \text{ AU} = 5 \text{ kV cm}^{-1}$ at $n = 21$.

The Stark structure of the alkali Rydbergs is still being actively investigated. One can do higher order perturbation theory⁸, diagonalisation with a truncated basis set⁹, or other approximate calculations⁷.

Because of their relatively small binding energy, Rydberg atoms can be readily ionised by electric fields. We write the potential for a Rydberg electron as $V = -1/|r| - Ez$ (see Fig. 2) and find that it has a maximum value $V_{\text{max}} = -2\sqrt{F}$ at $z = 1/\sqrt{F}$. An electron with energy $-1/2n^2 > V_{\text{max}}$ can escape. The condition for field ionisation is thus $F \geq 1/(16n^4)$ which occurs at $F = 10^{-6} \text{ AU} = 5 \text{ kV cm}^{-1}$ for $n = 15$.

Of course, field ionisation is not quite so simple. First, some electrons occupy states with wave functions concentrated away from the saddle-point produced in the potential by the electric field. They may have enough energy to field ionise, but do not sample the potential at the right place. Also, electrons with insufficient energy to ionise classically may escape by tunneling under the barrier. Further complications arise from the mixing of the wave functions by the field resulting in excited states that are superpositions of zero-field eigenfunctions. Field ionisation is a separate topic of serious investigation¹⁰.

Experimental description

The apparatus needed for the experimental study of Rydberg atoms is modest by comparison with other experimental facilities¹¹. One begins with a simple beam apparatus, consisting of a small stainless steel oven that can be heated to a few hundred degrees, contained in a vacuum system of characteristic linear dimension 0.5 m. Although some metals require a heat pipe oven, and some Rydberg spectroscopy has been done on rare gases which require no oven, the system described above is the most common. The atomic beam is collimated by a series of apertures and crossed by one or more laser beams which enter the vacuum system through appropriately placed windows (see Fig. 3).

At first it might seem that detection of Rydberg atoms could be very much the same as detection of other excited atoms: one simply looks at the radiation emitted when the atom decays to its ground state. More careful consideration reveals that Rydberg atoms do not decay very well by radiation, and in fact may have lifetimes long enough for the atoms to crash into the wall at the far end of the apparatus without ever emitting light. Transitions down to adjacent Rydberg levels are very weak and slow

because their frequencies are very low ($\Delta E = 1/n^3$) and spontaneous transition probabilities are proportional to the cube of the frequency ($1/n^9$). Transitions down to low lying or ground states, which have much higher frequencies, are very weak because the radial wave functions of Rydberg levels have very many oscillations and the integral of such oscillatory functions multiplied by one with only very few nodes is a small number, nearly zero. The result is that detection of Rydberg atoms by spontaneous emitted radiation is ineffective.

The usual procedure is to mount flat plate electrodes on either side of the atomic beam and apply a strong, d.c. electric field to the atoms. As the Rydberg electron is so far away from the nucleus and core, it is bound by a Coulomb field that is quite weak and it can easily be pulled away by the applied field and detected. Field ionisation, as described earlier, is very efficient for Rydberg atom detection.

Figure 3 shows a typical apparatus. The tuneable lasers are pumped by powerful beams from nitrogen or Nd:YAG lasers. The lasers are tuned to the transitions of interest and directed into the apparatus where they cross the atomic beam between the field plates. Time delay circuits triggered by the laser pulse apply the ionising field to the Rydberg atoms sometime after they have been created, and the detector measures the number of ions or electrons produced.

Applications of Rydberg spectroscopy

The signals are typically studied as a function of laser frequency, applied d.c. electric⁹ or magnetic fields^{15,16}, applied r.f. or microwave fields¹²⁻¹⁴ (which induce transitions between fine structure levels or to other Rydberg levels), background gas pressure¹⁷, or combinations of these and other influences. Figure 4 shows signals taken as a function of laser frequency at different values of applied electric fields (much smaller than the ionising field)¹⁸. Each vertical line is a wavelength scan taken at a different value of the applied electric field. The Stark spectrum of the sodium atom is dramatically laid out in Fig. 4.

The new knowledge which has come and will continue to develop from the study of Rydberg atoms spans many areas of atomic physics. For example, Stark shifts are greatly enhanced in highly excited states because the electron wave function is spread out over such a large region. The n^6 dependence described by equation (14) predicts a quadratic Stark shift of about $2 \times 10^{-3} \text{ AU} = 405 \text{ cm}^{-1}$ for an $n = 35$ atom in a field of $10^{-6} \text{ AU} = 5 \text{ kV cm}^{-1}$. As modern pulsed dye lasers can easily resolve 0.1 cm^{-1} (continuous wave (c.w.) dye lasers can resolve $3 \times 10^{-5} \text{ cm}^{-1} = 1 \text{ MHz}$), the Stark shifts arising from fields as small as 80 V cm^{-1} are quite noticeable in pulsed laser spectra, and from stray fields as small as 1.5 V cm^{-1} in c.w. (or r.f.) spectra. The Stark spectra of Rydberg states of several alkalis have been recently studied and described in detail¹⁸.

The Zeeman effect has no such spectacular enhancement. The magnetic shift of atomic energy levels is proportional to the Lande g -factor which depends only on the spin and the angular part of the wave function $Y_{lm}(\theta, \phi)$, and varies by no more than a factor of three over almost all atomic states. However, we have seen that the diamagnetic term or quadratic Zeeman term becomes important because of the large area (proportional to n^4) of the electron orbit. Diamagnetic effects of atoms in low lying states can only be observed in extraordinarily large magnetic fields, but for Rydberg atoms the effects are easily measured in laboratory fields^{15,16}.

When atoms are subjected to extremely strong electric or magnetic fields, that is, those fields which produce forces comparable to the Coulomb binding force, their structure is markedly changed. When the external field is so large that it can no longer be considered a perturbation, the ordinary solutions to the Schrödinger equation are not even approximately right. Theoretical studies of atoms in such conditions have been

stimulated by interest in plasma and astrophysical problems, but experimental measurements have not been done because laboratory fields can not be made large enough¹⁹. Rydberg atoms can provide a testing ground for the theories of atoms in strong fields because laboratory fields can easily be made to satisfy the strong field condition. We have already seen that field ionisation, that is, the process of atoms being torn apart by an external field, is a routine phenomenon in Rydberg studies. Further experiments should provide insights into the behaviour of matter at the surface of neutron stars (magnetic fields $\approx 10^{12}$ G) and in hot plasmas (very strong electric fields).

Fig. 4 The Stark spectrum of sodium (taken from ref. 18).

Spontaneous radiative transitions between Rydberg levels are very slow because the rate is proportional to the cube of the frequency, but stimulated transitions can be fast because the rate depends only on the strength of the radiation and the transition moment (square of the dipole matrix element) between the two levels involved. As the transition moment between two Rydberg states is very large (proportional to n^4), the rate is also very large and minute amounts of power are required to induce transitions. It is, therefore, fairly easy to do r.f. or microwave spectroscopy on these atoms^{12,13}. In fact, the matrix elements are so large that power broadening is difficult to avoid, and higher order transition processes (two or more quanta) occur readily.

There are many different kinds of r.f. experiments to be done. For example, r.f. spectroscopy of Rydberg atoms can produce high precision measurements of atomic parameters because of the very narrow linewidths (long lifetimes) of the transitions²⁰. One might measure fine structure splittings¹⁴, quantum defects, hyperfine interactions, or even fundamental constants by careful experiments on Rydberg atoms. Also, even in a moderately strong r.f. field, very high order processes (multi-photon) are easily observable²¹. Not only can these be used for spectroscopic investigations, but also for the testing of theories of ground state atoms in very strong optical frequency fields (high intensity laser light).

As transitions between Rydberg states can be induced by very tiny amounts of radiation, one must consider all possible sources in the description of such experiments. Although the power density of black-body radiation at room temperature is extremely small and is normally only considered in low temperature experiments, careful calculations and observations have shown that this radiation can appreciably shorten the lifetime of highly excited states by stimulated transitions²². One also expects that cooperative effects such as super-radiance and maser action may also be possible in a sufficiently dense population of Rydberg atoms.

The enormous transition moments of Rydberg atoms can be exploited to make sensitive detectors of low frequency radiation²⁰. As transitions can be detected by selective field ionisation, each quantum absorbed from an IR or microwave field produces a charged particle which can be readily detected. The result is a high efficiency, low noise, tuneable (via Stark effect), quantum detector of great interest in low temperature studies, astrophysics, communications, and so on.

A beam of atoms in Rydberg states can be thought of as transporting very low energy electrons at nearly uniform speeds. It is very difficult to make an electron beam monochromatic because of the thermal energy spread of the source, but Rydberg atoms divide the thermal energy between the electron and the very heavy nucleus so that the velocity distribution is very narrow. Collisions can be made either with Rydberg atoms directly on the target or by gently photoionising the highly excited electron and using it alone on the target. The resolution of electron collision studies on gases, beams and surfaces will be greatly enhanced by the use of Rydberg atom electron sources.

The previous discussion above has been restricted to Rydberg states of alkali metal atoms. It is possible to study the Rydberg states of molecules²³ or atoms with two or more valence electrons²⁴ (such as alkaline earths) and the added richness of the spectra provides new information. For example, after one electron is promoted to a Rydberg state, a second electron can be raised to one of the ion core's excited states. The atom now has too much internal energy to remain bound and autoionises, emitting an 'Auger electron'. This process may be enhanced by configuration interaction with another nearby state and precise studies can be made. A relatively new theoretical structure called multichannel quantum defect theory (MQDT) has been developed to describe these processes²⁵ which can be measured carefully and cleanly by Rydberg spectroscopy.

Conclusion

This discussion of the physics derived from Rydberg spectroscopy cannot be complete because of both the breadth of the field and its rate of development. There are a great many other topics which could not be included here because of space limitations. We have seen that many of the properties of Rydberg atoms can be accurately described by classical or very simple quantum mechanics, and that the apparatus for experimental studies is relatively small scale and inexpensive. Such simplicity makes the field very attractive, especially in view of the extraordinarily broad range of topics which can be investigated with these unusual atoms.

 $^{230}\text{Th}/^{234}\text{U}$ dating of travertine from the Bilzingsleben archaeological site**Russell S. Harmon^{*}, Jerzy Głazek[†] & Krystian Nowak[‡]**^{*} Isotope Geology Unit, Scottish Universities Research and Reactor Centre, East Kilbride, Glasgow G75 0QU, UK[†] Institute of Geology; [‡] Institute of Archaeology, Warsaw University, Warsaw, Poland

$^{230}\text{Th}/^{234}\text{U}$ dating of travertine from Bilzingsleben, places an absolute age of $228,000 \pm 17,000$ yr BP on the hominid remains and artefacts at this important archaeological site. Associated floral and faunal fossil assemblages are of interglacial character indicating a depositional climate slightly warmer than at present. These two facts permit correlation of the Bilzingsleben deposits with 'Stage 7' of the marine oxygen isotope record and the penultimate interglacial observed in the European and North American speleothem records.

THE absolute age and stratigraphic position of most of the hominid-bearing deposits of western and central Europe are, at present, uncertain outside the $\sim 40,000$ yr BP limit of conventional ^{14}C dating. Many of these archaeological sites contain coeval inorganically precipitated calcium carbonate deposits which can, under certain circumstances, be dated by natural disequilibrium within the uranium decay series. For example, U-series dating techniques have been used by Turekian and Nelson¹ to date the travertine sequence at Caune de L'Arage, France, at $96,000 \pm 10,000$ yr BP, and by Schwarcz and Debenath² to obtain an absolute age of $146,000 \pm 16,000$ yr BP for skeletal remains in bed 11 of the l'abri Bourgeois-Delaunay rock shelter at La Chaise, France. Here we report $^{230}\text{Th}/^{234}\text{U}$ age determinations for the fossiliferous hominid- and artefact-bearing travertine deposits at the Bilzingsleben site in the German Democratic Republic and briefly discuss the stratigraphic and archaeological significance of this age determination.

The Bilzingsleben site (Fig. 1) is located in the northern portion of the 'Middle German Highlands' about 35 km north of Erfurt in the type-region of the northern European Pleistocene glacial stratigraphic sequence. The archaeological deposits, from which a fossil human skull was first described by von Schlotheim³ in 1818, occur in the Steinrinne travertine quarry

capping an isolated plateau of Triassic (Lower Keuper) marls and dolomites at 35 m above the Wipper River. This plateau has been partially dissected by river entrenchment with four distinct Pleistocene gravel terraces present at elevations of about 30, 20, 10 and 2–5 m within the river valley. Traditionally these terraces have been assigned, in descending order, to the Elsterian, Saalian, Warthian, and Vistulian glaciations⁵. The travertine and associated silts in the quarry fill a lake depression over the highest (30 m) terrace which was formed as the result of subsidence of a karst sinkhole. A schematic section through these deposits is shown in Fig. 2. Directly overlying the gravels of the 30 m terrace are 3–5 m of a slightly eroded silt with furrows in the erosional surface infilled with peatearth and gley soil. Above this is a 4–8 m thick travertine deposit consisting of the following lithologic sequence:

- (1) 30–50 cm of 'sandy' dense, light-brown travertine containing abundant fossils, artefacts and hominid remains;
- (2) 50–80 cm of lacustrine limestone;
- (3) 30–40 cm of 'soft' porous travertine;
- (4) 300–600 cm of 'dense', dark-brown travertine.

Previous studies^{6–8} have shown that calcium carbonate speleothems and travertines can be confidently dated by U-series methods if they contain trace amounts of U, but are free of

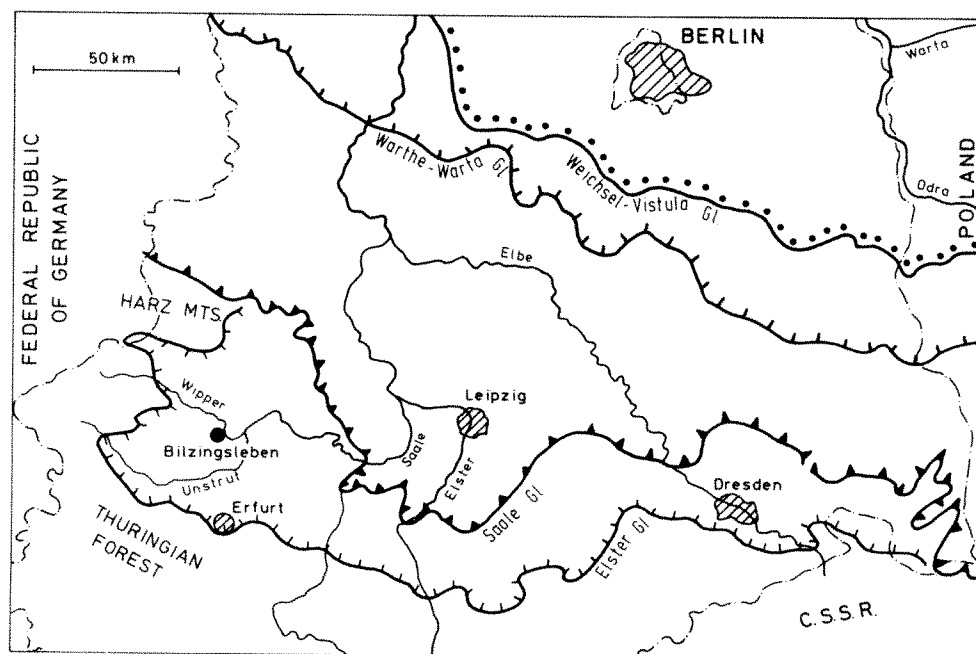

Fig. 1 The limits of continental glaciations in the southern part of the GDR (simplified after Cepek³) in relation to the Bilzingsleben archaeological site.

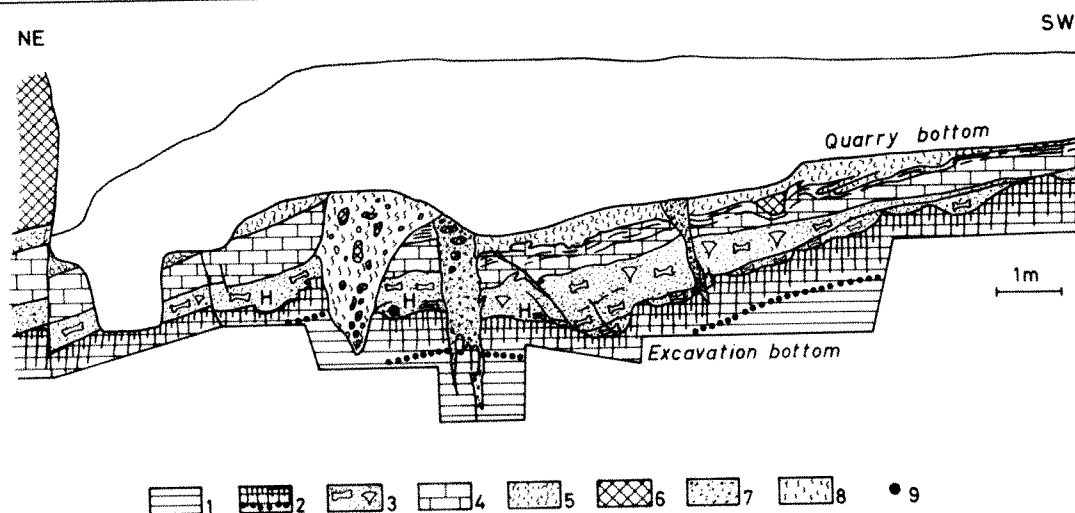

Fig. 2 Schematic cross-section of the travertine sequence in the Steinrinne Quarry near Bilzingseben (simplified after Mania⁵). 1, Silts; 2, soil profile on silts (black on top: gley horizon, vertical dashes: peat earth, black spots in bottom: illuvial carbonate concretions); 3, 'sandy travertine'—hominid—artefact—and bone-bearing layer; 4, lake limestone; 5, soft travertine; 6, hard upper travertine; 7, fissure filling with travertine debris; 8, loess with travertine debris; 9, dated travertine sample; H, location of hominid bone fragments.

detrital Th or Pa. In such instances, absolute dating is possible within the time range ~5,000–350,000 yr BP provided the carbonate is dense and impermeable primary calcite or aragonite showing no signs of diagenetic alteration or post-depositional leaching. The Bilzingsleben travertine which we have dated by the $^{230}\text{Th}/^{234}\text{U}$ method occurs as a dense lens of light brown, micritic calcite within the fossiliferous lower, 'sandy' travertine horizon (Fig. 2). The travertine lens is neither a later (younger) intrusion into the bone-bearing unit, nor is it a detrital clast of unknown age. The stratigraphically younger upper, dark-brown travertine unit was not suitable for dating because it contained a substantial admixture of detrital sediments and iron oxides. Four crushed samples of about 50 g were dissolved in dilute nitric acid and chemically pure U and Th isolated by coprecipitation ion-exchange, and organic solvent techniques^{9,10}. $^{230}\text{Th}/^{234}\text{U}$ ages were calculated from yield and background corrected isotope activities as measured by α spectrometry-pulse height analysis. Analytical data and calculated ages are presented in Table 1. Note the high degree of internal consistency for U concentrations ($4.3\text{--}5.0$ p.p.m.), $^{234}\text{U}/^{238}\text{U}$ ratios ($1.19 \pm 0.02\text{--}1.24 \pm 0.02$), and $^{230}\text{Th}/^{234}\text{U}$ ratios ($0.91 \pm 0.02\text{--}0.93 \pm 0.02$) as well as the high $^{230}\text{Th}/^{232}\text{Th}$ ratios (34–202). This indicates that all ^{230}Th activity in the travertine was authigenic and that it had not been subject to post-depositional loss or addition of U, thus giving us confidence in the $^{230}\text{Th}/^{234}\text{U}$ age determination of $228,000 \pm 17,000$ yr BP.

The stratigraphic age of the Bilzingsleben deposit has been debated for over 50 years. Geological relationships indicate that

the travertine sequence and associated archaeological materials must be younger than Elsterian in age, but there is no other consensus. The interglacial character of the deposit is well established from the abundant floral and faunal fossil material contained in the hominid-bearing, lower travertine unit. Some 10 species of plants, 15 species of snails, and 12 species of vertebrates have been recognised^{5,11–14}. These are listed in Table 2. Ecological interpretation of this fossil assemblage suggests a forest environment with a climate slightly warmer than at present with mean annual temperature elevated by about 2 °C and without winter frost (ref. 15 and A. Sutcliffe, personal communication).

Our radiometric age of $228,000 \pm 17,000$ yr BP permits direct correlation of the Bilzingsleben travertine with 'Stage 7' of the marine foraminiferal oxygen isotope record¹⁴ and the penultimate interglacial period in the North American¹⁷ and European^{18,19} speleothem chronologies (Fig. 3). However, placement of the deposit within the north-central European glacial stratigraphic sequence is more problematic. Although contemporaneity with the Lublin Interglacial in Poland (dated at $245,000 \pm 45,000$ yr BP) (ref. 20) and the Odintsovo (Kaydaki) Interglacial in the western USSR (dated at $227,000 \pm 28,000$ (ref. 21) and $236,000 \pm 25,000$ (ref. 12) yr BP) is suggested on the basis of thermoluminescence ages for these deposits, further correlations of this kind are not possible because of a lack of absolute age data. At some time the Bilzingsleben deposit has been assigned to the Elster-Saale (Holstein)^{5,15,23,24}, Saale-Warthe²⁵, or Warthe-Weichsel (Eem)^{13,26} interglacial periods.

It is generally accepted that the Eemian interglacial deposits of Denmark are correlative with 'Stage 5' of the marine oxygen isotope record so that the Bilzingsleben deposit cannot be of last interglacial age. Similarly, a Holsteinian age is ruled out if the arguments of Kukla²⁵ that the Saale ground moraines are at least of 'Stage 8' (and more likely of 'Stage 10') age are accepted. Cepek²⁵ has argued that the Rügen deposits represent an interglacial period between the Saalian and Warthian glacial events, but both the position and nature of this deposit are controversial. The Rügen deposit may, in fact, be correlative with the Bilzingsleben deposits, but there is insufficient evidence to justify such a claim. Therefore, we propose to establish the Bilzingsleben deposit as the type section for the penultimate interglacial period in north-central Europe because the age and interglacial character of the deposit are now firmly established.

Hominid remains from Bilzingsleben were noted as early as 1818 (ref. 4). Since 1969 excavation by the Landesmuseum für Vorgeschichte, Halle a. Saale has produced over 60,000 flint artefacts as well as rock, bone and antler tools⁵. Most of this material is without typology although some Mousterian and Tayacian artefacts have been recognised leading Toepfer²⁶ to assign a Pontiano-Mousterian character (similar to that of

Saccopastore) to the Bilzingsleben artefacts. More recently a Clactonian character for the artefacts has been suggested⁵. Recently discovered hominid bone material^{5,23,24,28} consists of os occipitale, os frontale and one molar. Taxonomic analysis by Stringer *et al.*²⁹ suggests that these hominid fragments represent an archaic form of Middle Pleistocene *Homo sapiens*, although exhibiting some more primitive morphological features which have led Vlček³⁰ to classify them as a new subspecies of *Homo erectus*. The fossils are similar in form to those from Vértesszöllös, bear some resemblance to those from Petralona, Steinheim, and Swanscombe, but are distinctly less evolved than the hominids at Saccopastore, La Chaise and Ehringsdorf²⁹. The samples of the lower travertine unit dated here are directly associated with the Bilzingsleben fossils and artefacts (Fig. 2) and thus an age of 228,000 $\pm 17,000$ yr BP can be assigned to this archaeological site.

This age determination has important implications as regards Middle Pleistocene hominid evolution. It is widely assumed that *Homo erectus* evolved into *Homo sapiens*, but the fossil evidence is equivocal. If Vlček's³⁰ contention that the Bilzingsleben fossils represent a new subspecies of *Homo erectus* and the somewhat dubious U-series ages of ~200,000–220,000 yr BP for the Ehringsdorf lower travertine unit^{8,27,31} are accepted, then it must be concluded that *Homo erectus* and *Homo sapiens* coexisted in central Europe during the penultimate interglacial period or that our present concepts of variation within these hominid species have to be considerably revised. If not, then morphological differences between the primitive hominid form of Petralona, the archaic forms of Bilzingsleben and Vértesszöllös and the more advanced forms of Ehringsdorf, La Chaise, and Saccopastore could represent progressive transitions within a single lineage of *Homo sapiens*. Between-site morphological differences (for example compare Swanscombe and Steinheim with Bilzingsleben and Vértesszöllös) would then be explained in terms of both phyletic change and sexual dimorphism within individual populations which may be superimposed on temporal, geographic and population variations²⁹.

Nevertheless, from the absolute age data presented here, and similar archaeometric studies from France^{1,2} and Greece⁸, it is evident that the archaeological correlations predominantly based on the antiquated concept of only four Pleistocene glaciations must be revised. It is evident that (1) many Middle Pleistocene archaeological deposits (such as that at Bilzingsleben) assigned on meagre and equivocal field evidence to a particular interglacial period, may be miscorrelated and, in fact, represent

Fig. 3 Comparison of the Bilzingsleben age with the marine foraminiferal oxygen isotope record of Shackleton and Opdike¹⁶, and the North American speleothem chronologies of Harmon *et al.*¹⁷, Atkinson *et al.*¹⁸ and Harmon¹⁹ establishing a penultimate interglacial age for deposition of the Bilzingsleben travertine.

an interglacial event not necessarily recognised in the European terrestrial glacial stratigraphic record, and also that (2) supposed Holsteinian deposits may belong to two or more interglacial periods. Further archaeometric studies of the type described here are required to resolve both of the ambiguities relating to the correlation of European prehistoric cultures and industries (for example, the three different ages for the British Acheulian cited by Collins³²) and are necessary to clarify further the pattern of hominid evolution in Europe (where there is increas-

ing evidence to suggest that *Homo erectus* and *Homo sapiens* may have coexisted during the Middle Pleistocene).

This research was made possible by a joint exchange programme between the Universities of Warsaw and Glasgow. The Isotope Geology Unit is supported by a grant from the NERC. We thank D. Mania for assistance with sample collection, and T. Wysoczański-Monkiewicz, C. Turner, C. B. Stringer and A. Sutcliffe for helpful discussions. The manuscript was typed by Mrs E. Yuill and figures drawn by A. Kozłowski and J. Bennett.

The crack–seal mechanism of rock deformation

John G. Ramsay

Geologisches Institut, ETH, Zentrum, CH 8092 Zurich, Switzerland

Many naturally deformed crustal rocks contain mineral-filled extension veins. The crystals making up the vein filling often show a fibrous habit and seem to be built up by a succession of 'crack–seal' increments: the elastically deforming rock fails by fracture, and the walls of the open micro-crack are sealed together by crystalline material derived by pressure solution in the rock matrix.

MANY of the rocks deformed by natural tectonic processes that have occurred in the upper 30 km of the Earth's crust show the development of more or less regular systems of extension cracks and fissures, the fissure spaces filled with silicate or carbonate minerals. The mechanisms by which such veins develop is of special interest to our understanding of crustal deformation. In many orogenic regions extension fissures can apparently give rise to large finite elongations and they can lead to finite strains of several per cent, locally exceeding 50%. The evidence presented here suggests that many, if not most, of these extension veins are formed by an accretionary process involving the formation of a narrow fracture followed by filling of the open space by crystalline material, a mechanism termed 'crack–seal'¹. Geometric features implying this mechanism have been most commonly observed in rocks deformed at metamorphic grades up to upper greenschist facies in environments where stress-induced chemical transfer (pressure solution) of materials seems to be relatively common. The minerals appearing in the vein fillings cover a wide range of mineral species (for example, quartz, calcite, feldspar, actinolite, biotite, and chlorite).

Early stages of vein formation: structure of narrow veins

The first example of the crack–seal process to be described here is taken from pisolitic ironstones of Lower Tertiary age situated

in the frontal folds of the Morcles nappe, one of the important units of the Helvetic nappes, near the village of Champéry, Valais, Switzerland.

The rock is a dense ironstone with sub-spherical, well layered chloritic ironstone pisolites up to 6.0 mm in diameter, and with scattered, isolated, rounded to sub-angular grains of clastic quartz. Figure 1a shows a single crack 45 µm wide passing through matrix, quartz grains and chamosite. The two sides of the crack have been joined together with silicate material; the separate fragments of quartz are sealed together with clear quartz in optical continuity with the broken, inclusion-rich quartz parent, whereas the chamosite grains and ironstone matrix are sealed with fibrous green chlorite. Figure 1b illustrates a vein built up by repetitions of this cracking and sealing process. Eleven small veinlets, each of ~45 µm width, group together to form a compound vein which in the rock specimen appears to the naked eye as a single white vein 0.5 mm in width. The optical control of the successively formed veins by the separated pieces of wall rock is very clear. In the thin sections the successively sealed veinlets give rise to very characteristic 'wing'-like slots of new quartz which in three dimensions have a 'Saturn ring'-like form (Fig. 2). It seems that successive cracks took place along the vein–matrix contacts of a previously sealed crack system, that often a small amount of wall rock material was detached during each successive crack, and that this wall material was preserved as an inclusion trail between the cracks marking successive incremental extensions (Fig. 1c). The cracks

Fig. 1 *a-d*, Thin sections of crack-seal veins in a sandy pisolitic ironstone: *a*, single quartz-chlorite filled crack passing through clastic quartz and chlorite grains; *b*, an array of several small crack-seal veinlets making up a single compound vein; *c*, detail from *b* showing inclusion bands parallel to the main vein wall, the general optical continuity of vein filling with the parent grain in the vein wall, and one crack-seal band (darker grey) slightly misorientated to the other bands; *d*, characteristic 'sawtooth' contacts between elongated fibrous quartz crystals. *e, f*, Thin sections of calcite filled crack-seal veins in oolitic and organic clastic limestones. All scale bars, 100 μm .

occur along the previous vein contacts because this is the overall mechanically weakest surface in the rock.

Although successively grown new quartz strips are generally in optical continuity with the parent quartz, occasionally a misfit of *c*-axis of up to about 3° is seen (Fig. 1*c*). These misfits probably occur because the new growth in a veinlet may be guided by a slightly misorientated seed fragment of broken wall. Where the successive cracks pass along the margin of a quartz grain the inclusion trails so derived are rich in dark iron-rich matrix components, whereas where a crack passes through the centre of a quartz sand grain, the wall-derived inclusions consist mostly of quartz and are visually not so striking. However, the margin of an internally broken quartz grain which has undergone successive fracture and sealing shows a very characteristic saw-tooth form (Fig. 1*d*).

The second example of the crack-seal mechanism is taken from a quite different rock type. The rock is a bioclastic limestone of Jurassic age from the Clariden region of central Switzerland. The limestone sequence is in part oolitic, and in part consists of fragments of shells, crinoids and other organic debris. Figure 1*e* shows a single extension crack passing through an oolitic limestone. The crack sometimes passes directly through the ooids and the matrix, and in places it seems to have been guided by the mechanically weaker boundaries of the oolitic particles. It has been filled with small crystals of clear, crystalline calcite which grow in optical alignment with small

calcite crystals making up the ooids and their matrix. Figure 1*f* shows a succession of calcite sealed microcracks separated by very narrow zones of inclusions of screens of wall rock material, producing an overall vein structure which is remarkably similar to that of the sandy ironstone of the first example. It is especially remarkable that the width of the microveins in the two examples is almost the same, and that the optical orientations of the calcite crystals passing through the composite veinlet aggregate is continuous across the veins, as was the optic orientation of the quartz joining the fragments of broken sand grains.

Crack-seal structure in large veins

The third example of the crack-seal process is a very spectacular one, and illustrates especially well the way that the seal material is added on the walls of the previously formed crack. It comes from highly deformed ferruginous limestones of middle Jurassic age from the Windgällen situated in the autochthonous cover rocks of the Aar Massif of central Switzerland. The limestones contain chamosite oolites and are sufficiently rich in haematite and magnetite to have been mined for their iron content in the latter part of the nineteenth century even though they are situated at an elevation of 2,400 m. The tectonically formed veins are found along planes sub-perpendicular to the direction of maximum finite stretching as determined from the shapes of the deformed oolites^{2,3}. The veins (Fig. 3) consist of fibrous intergrowths of quartz and calcite, the fibres being orientated

perpendicular to the walls of the veins. The veins have the characteristics of antitaxial vein growth⁴—that is, the crystals grow from an approximately centrally located inclusion-rich zone (the median surface) towards the two walls. Some of the individual crystal fibres become larger towards the walls, presumably because they were more favourably orientated for growth than their neighbours.

The most remarkable feature of these antitaxially formed veins is the presence of very regularly orientated lines of solid inclusions, mostly consisting of tiny crystals of chlorite and calcite arranged sub-parallel to the walls of the vein at distances of about 12 μm apart. These lines of inclusions are termed inclusion bands (Figs 3, 4b, 4c). The undulations seen in one inclusion band are more or less parallel to those in the adjacent bands, but the undulations gradually change shape from inclusion bands in the vein centre to those near the vein wall (Fig. 4b). The inclusion bands close to the wall are parallel to the vein-wall contact (Figs 3, 4b). As well as a correspondence of shape between adjacent inclusion bands there is also a striking correspondence in inclusion composition and grain shapes of the individual crystals making up the bands. This is particularly noticeable within calcite inclusions; these form lines of separate, optically parallel and shape related grains aligned sub-perpendicular to the vein wall, termed inclusion trails (Figs 3, 4c, 4d, 4f). In many instances these small grains can be shown to be completely enclosed in the larger fibrous grains of the main host vein crystal, and under the microscope it can be proved that there could have been no direct physical connection with some parent grain located outside the plane of the thin section (such as occurs when a section passes through the edges of the Saturn-ring structure of the crack-seal grains of our first example, shown in Fig. 2). In a few inclusion trails the individual inclusions come very close to each other, and some do form series of more or less continuously linked crystals (Fig. 4d). The composition of crystal components of adjacent inclusion bands change sympathetically (Figs 3, 4c). An inclusion band made up of chlorite particles will change along its length to one made up of calcite crystals, and adjacent bands show identical changes in composition (Figs 4c, 5). The compositional changes along adjacent bands always occur along a line parallel to the inclusion trails. The mineral component changes can be related to the composition of the vein-matrix wall; the inclusion trails of calcite always

root on to the normal granular carbonate of the rock wall, whereas the chlorite inclusion trails always root on to a wall made up of the broken surface of a green chlorite ooid. The trails of optically parallel calcite inclusions lead to an optically identically orientated clear calcite crystal growing on the vein-matrix wall and which itself is optically aligned to a more opaque carbonate fragment of the matrix (Figs 4f, 5).

Fig. 3 Schematic diagram to show the main features of quartz-calcite tectonic veins in the oolitic limestone of the Windgällen. The vein on both sides of the median surface shows inclusion bands and inclusion trails, but these have been omitted on the upper side of the median surface so as to show the general shapes of the main vein-forming minerals.

Fig. 2 Schematic development of crack-seal veins. The left-hand side shows the appearance of successive crack-seal veins in cross-section, while the right-hand side illustrates what is believed to be the three dimensional Saturn-ring structure deduced from successive two dimensional thin sections.

The relationships of the large fibrous quartz and calcite crystals forming the main vein filling to each other and to the small crystal inclusions is in main geometric features simple, but, in detail, quite complex. In general the grain-to-grain contacts of the larger crystals are sub-parallel to the inclusion trails (Figs 3, 4d). Calcite and chlorite inclusion trails and bands can be formed in both quartz and calcite forming the larger vein-crystals (Fig. 4f, calcite in quartz, and calcite in calcite in the dark centrally located grain; Fig. 4c, chlorite in quartz and chlorite in calcite). The chemical control on the composition of the inclusion crystals seems to be exerted by the composition of the matrix at the vein-matrix wall and not by the composition of the main vein crystals. Although the contacts of large vein-forming crystals are generally almost parallel to the inclusion trails in several examples the inclusions forming a trail transect these contacts passing from one large main vein crystal to another (Figs 3, 4d, 5). The quartz-quartz, quartz-calcite and calcite-calcite contacts of the main vein crystals often show a saw-tooth shape (Figs 4b, 4d, 5), the dimensions of the irregularities being the same as those of the inclusion band spacing. Although the large vein-forming crystals linking across the inclusion bands are generally optically continuous (Figs 4e, 4f), some slight irregularities do occur in the optical parallelism between certain inclusion bands. Variation in *c*-axis orientation

of up to 3° gives rise to a gently undulating dark-line polarisation colour appearance under crossed polars (Fig. 4c), and in a few instances slight variations of *c*-axis orientation in a single large individual crystal seems to be the result of plastic deformation after crystallisation (Fig. 4b).

The remarkable geometric features of these veins have been described in detail because they seem to provide a key to the understanding of vein-growth by the crack-seal mechanism. The inclusion band and inclusion trail structure seems to be best explained with recourse to progressive incremental cracking along the vein-matrix contacts, followed by a sealing together of the crack walls by crystalline material precipitated from a fluid phase. The successive microcracks were filled with fluids containing components in solution which were chemically closely related to the components forming the main body of the rock, and which were probably derived by local chemical solution and transfer (pressure solution). Some of these components (Ca^{2+} , CO_3^{2-} , Mg^{2+} , Fe^{2+} , Fe^{3+} , Al^{3+} , Si^{4+}) were then precipitated by syntaxial overgrowth on the crystals making up the microcrack walls as new formed calcite and chlorite. Some of the wall rock calcite crystals were favourably orientated for rapid growth (see, for example, Fig. 5, calcite in trail C_{14}) and could form a complete wall to wall link between the two sides, whereas others (Fig. 5, crystals in trails C_{11} , C_{12} , C_{13} , C_{15}) did not grow so fast and were therefore cut off by other faster growing crystal components before they could form a cross-link. The main crystal components which make up the continuous long fibres

(Fig. 5, quartz Q_1 , Q_2 , Q_3 and calcite C_1) were nucleated in the first formed crack, and because newly forming cracks always develop along the mechanically weak contacts of earlier formed veins, successive additions of new material lead to fibrous growth of these crystals away from the initial vein (antitaxial growth). These crystals can only grow sideways parallel to the vein at the expense of less favourably growth orientated neighbours. These space competing neighbours might be of the same mineral species (Fig. 5, quartz grain Q_2 growing at the expense of grains Q_1 and Q_3) or of a different species (calcite grain C_1 growing at the expense of quartz grain Q_3 and including unfavourably orientated calcite C_{15} on an inclusion trail). The crystallisation of the main vein component usually leads to a complete solid seal across the walls, but occasionally one finds remnants of fluid phases preserved as small fluid-gas bubble inclusions or negative crystal fillings. The fact that crystallisation of solid proceeds to form a complete wall-to-wall seal implies either that fluid containing the source of solid in solution must continually flow through the fissure, or that there is a continual replenishment of solid phase from the vein walls into the fluid phase occupying the progressively filling fissure. Once the sealing of the walls of the microcrack is complete, tectonic stresses are able to be transmitted across the vein and its walls once more. The intensity of these stresses builds up until a critical level of stability is achieved. The vein matrix contact then fails and a new fracture space is developed whose dimensions are controlled by the elastic recovery of the stressed walls. The

Fig. 4 Thin sections of crack-seal veins from the Windgällen, all taken with crossed polars. *a*, The chamosite ooids with characteristic concentric structures in a dark iron-rich matrix containing pale carbonate grains; *b*, inclusion bands parallel to the vein wall—chlorite inclusion bands occur where the wall of the vein is occupied by an ooid, whereas calcite inclusion bands are found where normal matrix carbonates are found along the vein walls (see Fig. 5); *c*, inclusion bands passing through large calcite and quartz crystals and changing in composition from chlorite components to calcite components (left to right); *d*, inclusion trails of calcite passing through quartz fibres; *e*, detail of calcite inclusion trails in quartz showing the remarkable shape similarity of the individuals making up an inclusion trail; *f*, calcite inclusion trails linking on to wall rock calcites with the same optical orientation. Fig. 5 Schematic diagram showing the main features of the inclusion band and inclusion trail structures in the Windgällen veins. Calcite crystals with line ornament, quartz crystals stippled.

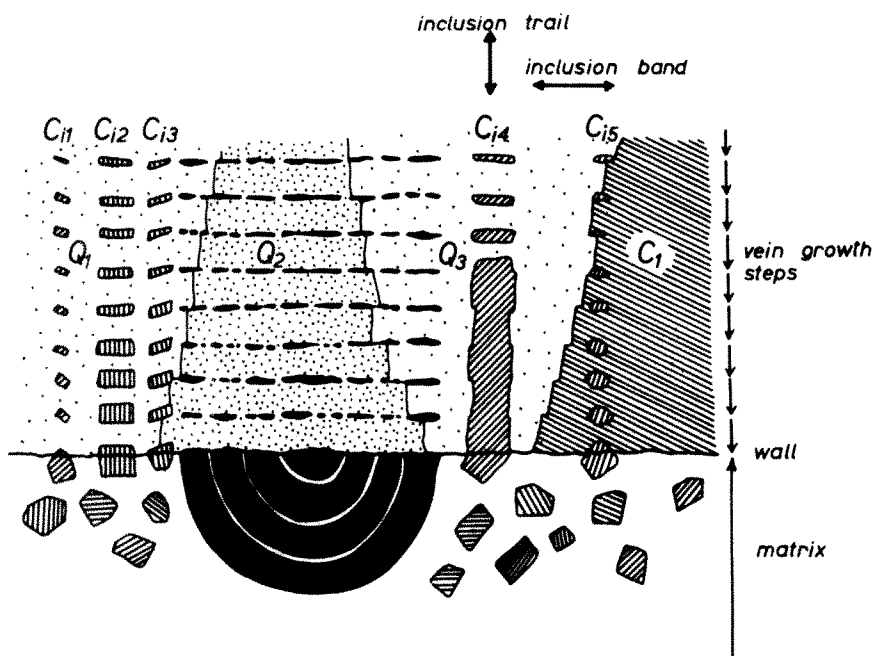

Fig. 6 Diagram showing the sequence of events leading to elongation of a rock by the crack-seal mechanism: *a*, elastic strain accumulation (σ_1 and σ_3 are greatest and least principal tensile stresses); *b*, development of first fracture and release of elastic strains in matrix, solution transfer

of material from walls into microcrack; *c*, seal of vein walls and further elastic strain accumulation; *d*, development of second crack and release of elastic strains in vein walls, further solution transfer with development of stylolitic surfaces; *e*, repeated crack-seal microcracks forming a compound vein; *f*, large finite shortening leading to vein buckling and the formation of stylolites both outside and inside the compound veins.

process of sealing the walls is repeated, and the crack-seal cycle is repeated indefinitely providing that sufficient tectonic stress accumulates for cracks to develop or that sufficient material is available in the solution which fills the cracks to seal the walls together. The Windgällen veins described here show more than 500 increments in a total vein width of 7.5 mm.

Conclusions

Figure 6 gives a review of the sequence of events by which a large overall extension by the crack-seal mechanism can be achieved. Tectonically induced elastic strains reach a critical level, and then fracture occurs (Fig. 6, *a* and *b*). The mechanism which brings about tensile fracture is probably that termed hydraulic fracturing⁵⁻⁷. There is strong evidence from the later precipitation of materials in the fracture that a fluid phase was present during fracturing, and it is well established that tensile fracturing can be initiated when the fluid pressure equals the tensile strength of the rock. Fluid-filled open microfractures are formed which are later filled with crystalline material derived by pressure solution in the rock matrix and chemical transfer of this material into the low pressure fluid-filled space (Fig. 6*c*). The

process is repeated and new material is added antitaxially so that the vein walls of the initial vein accumulate new material. The outward growth occurs because, statistically, there are equal chances of new cracks forming and subsequent new sealing material developing on both vein-matrix walls (Fig. 6*e*). At high finite strains (say greater than 10% shortening) the veins themselves have to shorten. Vein shortening is accomplished by buckling or by the development of tectonic stylolites along the grain boundaries of adjacent previously crystallised fibres (Fig. 6*f*).

The use of synchrotron radiation in time-resolved X-ray diffraction studies of myosin layer-line reflections during muscle contraction

H. E. Huxley*, A. R. Faruqi*, J. Bordas†, M. H. J. Koch† & J. R. Milch††

*MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

†EMBL Outstation, c/o DESY, Notkestrasse 85, D-2000 Hamburg 52, FRG

Experiments on striated muscle have been carried out at the EMBL Outstation at DESY, Hamburg, using the electron-positron storage ring DORIS as a high-intensity X-ray source. The low-angle reflections from the myosin cross-bridges could be recorded more than 1,000 times more rapidly than with the best conventional X-ray sources, and could be followed during contraction with a time resolution of 10 ms.

DETAILS of the molecular mechanism which produces the sliding force between actin and myosin filaments during muscle contraction have proved difficult to establish. It has long been suggested^{1,2} that the force is developed by moving projections or cross-bridges on the myosin filaments which may undergo a cyclical process of attachment and detachment with sites on the actin filaments, but direct structural evidence for this mechanism is inherently difficult to obtain. Surviving muscles give informative low-angle X-ray diffraction diagrams³⁻⁵ which, in principle, can reveal details of cross-bridge behaviour during contraction. However, the use of this approach has previously been restricted by the long exposure times needed to record the patterns on film, although much useful information has been obtained⁴⁻⁹. Recently the use of increasingly efficient and sophisticated X-ray counters and electronic data handling systems has made it possible to carry out time-resolved measurements on the stronger equatorial and meridional reflections from striated muscles with a time resolution in the 10 ms range^{10-16,28,29}. This is the time scale required to make useful comparisons with normal tension development and decay in the muscles commonly used (for example, frog sartorius), but is too slow to study faster transient processes. Moreover, the off-meridional pattern of myosin layer-lines, which arises from the helical arrangement of the cross-bridges, is too faint to be recorded with adequate time resolution, even using very long contraction series, if normal laboratory-based X-ray sources are used.

For this and analogous reasons, there has recently been considerable interest in the use of synchrotron radiation as a high-intensity X-ray source for diffraction experiments^{17,18}. We report here some observations made at the EMBL Outstation at DESY, Hamburg, using the electron-positron storage ring DORIS.

Use of a two-dimensional TV detector

In our initial experiments we were concerned to establish whether or not the loss of layer-line intensity, which had earlier been observed (using film and laboratory X-ray sources) to occur during a very long series of tetanic contractions, was a genuine effect occurring during an unfatigued contraction in a freshly dissected muscle. We used a frog sartorius muscle, maintained in an oxygenated Ringer solution in the usual manner^{4,8} and stimulated directly by platinum electrodes lying along its length on either side. Tension was measured and recorded electronically. A focused and monochromatized X-ray beam was produced from the incident radiation from the storage

ring by a camera designed by Rosenbaum and Harmsen¹⁹, comprising an eight-element, totally reflecting glass mirror of total length 160 cm and a germanium curved crystal monochromator. With this apparatus, a good-quality layer-line pattern from muscle could be recorded on film in a few minutes, compared with about 24 hours for a similar quality pattern using a high-power rotating anode X-ray tube. In the actual experiments, however, the pattern was recorded on an X-ray image intensifier-TV detector^{20,21}, as this enabled good layer line data to be collected with a total exposure time of only 1 s. The two-dimensional nature of the detector had the great advantage that the whole of the X-ray pattern was available for inspection and measurement, and indeed the myosin layer-lines could be viewed directly in 'real time' on a monitor integrating over about 1 s. In this way, it was possible to see the pattern disappear as the muscle was stimulated tetanically for 1 or 2 s, and then reappear as soon as stimulation ceased. However, when collecting time-resolved data, only the pattern corresponding to one particular

Fig. 1 Layer-line pattern from resting frog sartorius muscle at 10 °C recorded on the position-sensitive counter. Background fitted using a fourth order polynomial; total exposure time 3 s. Layer-line spacings are indicated.

†Present address: Department of Physics, Princeton University, New Jersey 085400.

'time-slot' could be recorded in a given series of experiments because of readout time limitations with this type of detector.

To investigate the behaviour of the pattern during single twitches, we recorded the pattern during a time interval of 150 ms and in each run of 6–10 twitches this 'slot' was set at the same time during contraction. A total exposure time of 1–1.5 s was sufficient to record a good-quality pattern. The run was then repeated for a different time slice. Within this limited time resolution it could be seen that the disappearance of the layer-line pattern at the beginning of the twitch and its return during relaxation followed a time course very similar to tension development and its decay. This could be observed in quite short contraction series in which there was no doubt that the muscle was in good condition throughout and where there was none of the weakening of the resting layer-line reflections that we have observed in longer series of tetanic contractions, especially at lower temperatures; nor did we see the delayed return of off-meridional layer-line pattern after contraction apparent in very long contraction series¹³. Thus, the experiments showed unambiguously that the loss of the layer-line pattern is a specific and reversible accompaniment of normal contraction.

It was also noticeable, as observed previously⁴, that the decrease in intensity of the 14.3-nm meridional reflection was often much less marked than that of the off-meridional layer lines. Nevertheless, such muscles showed almost a complete disappearance of the 'forbidden' 21.5-nm meridional reflection during the peak of the twitch, and its reappearance during relaxation.

Intensity measurements with a one-dimensional detector

To compare the time course of the layer-line changes more accurately with that of tension, a different system was used. This used a position-sensitive one-dimensional proportional counter of the delay-line type, designed by Gabriel²². This was positioned over the muscle pattern with its axis parallel to the meridian but displaced sideways from it so as to record the strongest parts of the set of myosin layer-lines. When filled with a xenon-CO₂ mixture at 2 atm, the counter could record the first few layer-lines satisfactorily in a few seconds, giving a total of several thousand counts in the first layer-line after background stripping. (For stronger parts of the pattern, the beam had to be attenuated.) The delay line output was decoded using a direct time-digitising device (modified CERN modules DTD164 and 211)²³. The latter are read out by an auxiliary CAMAC crate controller designed by C. Boulin. This module stores the one-dimensional patterns in a memory linked to a PDP11/45 computer²⁴ in 10-ms time bins via a bin switching device designed and built by E. Dorrington. The time slots are synchronised electronically with the stimulation of the muscle. Details of this system will be described elsewhere. The X-13 camera²⁵ used in these later experiments is another mirror monochromator device again using an 8 × 20-cm section mirror but with a triangular-shaped monochromator which is bent into a section of circle by applying pressure at the apex²⁶. The specimen-to-detector distance was approximately 2.2 m.

With the storage ring operating in the dedicated mode at 3.185 GeV and 70–90 m/a (positrons only), with 480 bunches, total counting rates over one quadrant of the layer-line pattern were in excess of 10⁵ c.p.s. and adequate data could be collected in 10-ms time bins from a series of a few hundred single twitches spaced at 30-s intervals. Thus, a typical experimental run would last 2–3 h and gave a few seconds of total exposure time in each time bin.

In these experiments (and in the earlier ones) a fast-acting lead shutter was arranged so that exposure of the muscle to the X-ray beam was minimised, being kept to 2 or 3 min even in the longest runs. No evidence of radiation damage was apparent in these experiments. However, in test exposures exceeding 10–15 min, deterioration of both the X-ray diagram and the microscopic appearance of the region of the muscle in the X-ray beam was

Fig. 2 Changes in the 42.9-nm layer line intensity (□) and the relative tension (●) during a twitch in frog sartorius muscle at 10 °C. Data are summed from 900 twitches, each time slot being of 10 ms duration, that is, corresponding to 9 s total exposure. Time at which electrical stimulus applied to muscle is shown by an arrow. Incident intensity at specimen was reduced by a factor of 3 (using aluminium foils) because of total counting rate limitations (later overcome) in the electronic circuits at the time of this experiment.

quite obvious. As such radiation effects have not apparently been observed with glycerinated insect flight muscle, it may be that the radiation-sensitive component resides in the calcium-releasing mechanism.

Data could also be collected from a much smaller number of twitches if longer time slots were utilised (for example, 50 ms), but no changes in the behaviour of the pattern were noted over the experimental times used. Meridional data were also collected, usually from considerable shorter series of twitches, as the patterns are much stronger and have a higher signal-to-noise ratio.

The layer-line reflections are superimposed on a steeply sloping background (see Fig. 1). A computer program was used to draw in the best fit (least squares) of a polynomial to the background levels seen between the successive layer-line peaks. It was found that a third (or sometimes fourth) order polynomial gave a satisfactory fit. If a separate fitting operation was carried out for each set of data in successive time slots, it was noticeable that a slight increase in the background level occurred during contraction. However, the most striking change was the large decrease in all the layer-line intensities during the time that the muscle was developing tension. The time courses of the changes in all the layer-lines do not seem to differ significantly and for simplicity we will consider only the first and strongest of these, that at 42.9 nm. The results of a typical run at 10 °C are shown in Fig. 2, where the intensity of the reflection is plotted as a function of time after the stimulus of the muscle (by a single maximal shock), in 10-ms time channels. The isometric tension developed by the muscle is shown on the same time scale. It can be seen that the reflection begins to decrease in intensity within 20 ms of stimulation, falls almost to zero intensity (in some cases) by about 70 ms, and then returns to its resting value (or even slightly more on several occasions) after about 200–250 ms.

The relationship between change in intensity and tension is shown more clearly in Fig. 3, where the change in each of them is plotted as a percentage of the maximum change occurring. It can be seen that both during the onset of activity and during relaxation, isometric tension and change in X-ray intensity follow a markedly similar time course; this was the case in all the records we obtained (six good runs so far) although in one or two

Fig. 3 Changes in the 42.9-nm layer line intensity (\square) and tension (\bullet) plotted as a percentage of maximal change. Other conditions are the same as in Fig. 2 except that the total exposure for each 10-ms time slot was only 3 s.

a very slight lag in the X-ray pattern (≤ 20 ms) was noted during relaxation. We do not have sufficient data, however, to establish whether or not the intensity change leads the tension change during the rising phase of tension by a few milliseconds at this temperature, as it does in the case of the equatorial reflections¹⁴.

Measurements of the intensity changes in the 14.3-nm meridional reflection in exactly the same conditions showed a rather interesting effect (Fig. 4). The change in intensity of the reflection, plotted again as a function of time after stimulus, exhibited a pronounced biphasic behaviour. The initial decrease in intensity took place with essentially the same time course as that of the layer-lines, but this was followed by a slight recovery of intensity during the peak of the twitch and then a large decrease in intensity again during the relaxation phase. Thus, the 14.3-nm intensity fell to its minimum value when the tension and layer-line intensities had almost returned to their resting values, and it returned to its resting value with a pronounced lag behind tension recovery. This lag has been seen in many previous experiments (using laboratory X-ray sources) and the biphasic fall in intensity has also been seen previously, although less frequently. This effect might be due to a longitudinal disordering of the myosin filaments, which in a resting muscle are arranged with their sets of cross-bridges in register. This would have a much larger effect on the intensity of meridional reflections than on the off-meridional layer-lines, and the disordering might be maximal during the relaxation phase, when different regions of a muscle relax at somewhat different rates and when disorder of the sarcomere pattern is much more frequent and pronounced than at other times during the twitch. We hope to investigate the phenomena further in future experiments.

Muscles at 'no-overlap' length

We have also carried out some preliminary experiments on the behaviour of the layer-line pattern in frog semitendinosus muscles stimulated at very stretched lengths where overlap of thin and thick filaments is either completely abolished or very greatly reduced. In earlier work using film and laboratory X-ray sources, in which very long tetani (7 s) had to be repeated many hundreds of times over a period of a day or more to record the patterns, a substantial decrease in layer-line intensity was observed, but it was not known whether this was due to an activation mechanism in the myosin filaments themselves, or whether it was associated with a progressive disordering of the

sarcomere structure allowing actin-myosin interaction still to occur at these extended sarcomere lengths^{7,9}. In the present experiments, using both the image-intensifier system and the position-sensitive counter system, we were able to record the layer-line pattern given by these stretched muscles by summing over as few as 10 1-s tetani, so that the possibility of the 'creep' artefact was very much reduced.

In all our experiments so far we have found a very large reduction in the extent of decrease of the layer-line intensities from very stretched muscles during stimulation compared with that seen in similar muscles at normal sarcomere lengths, and in most of the experiments no decrease at all in intensity was observed. For technical reasons it was not possible to determine sarcomere lengths during these experiments, in which active tension was reduced to about 10% of its rest-length value, but as the ability to develop full tension (and to show the normal layer-line changes) was restored when the muscles were returned to resting length, it seems likely that the muscles were close to the non-overlap length and in good condition. Thus, we conclude provisionally that interaction with actin is necessary for helical disordering of the myosin cross-bridges to occur following stimulation. This agrees with recent observations showing an absence of radial cross-bridge movement at no-overlap sarcomere lengths, as judged by the absence of change in the equatorial X-ray diagram¹⁶.

Interpretation of intensity changes

The principal finding we will discuss here is the large decrease in intensity of the layer-lines at resting sarcomere lengths. When this was first seen in the earlier experiments using film and long series of tetanic contraction^{4,5}, it was interpreted as indicating a disordering of the regular helical arrangement of myosin cross-bridges (in resting muscle), brought about by their interaction with actin during contraction. This interpretation remains a very plausible one, and is reinforced by the fact that the change is so closely correlated temporally with tension development, and that the bridges return to their normal helical order around each myosin filament immediately tension disappears (at least in relatively short series of twitches at 10 °C). During the onset of tension, although the ends of the muscles were held fixed, there would be significant internal shortening of the muscle against series elastic elements, equivalent to at least a 2 or 3% change in

Fig. 4 Changes (plotted as a percentage of maximal changes) in the 14.3-nm meridional reflection (\square) and tension (\bullet) during a twitch from frog sartorius muscle at 10 °C. Total exposure is 1.5 s in each 10-ms time slot.

muscle length. This would correspond to several hundred angstroms of sliding movement between the overlapping actin and myosin filaments. Thus, if this movement was produced by a change in tilt of attached cross-bridges, we would expect to find the population of attached bridges distributed over all the possible angles of tilt, given the asynchronous nature of the interaction. This could explain why neither myosin type nor labelled actin type layer-lines are visible.

We consider, then, that these rapid and reversible changes in the myosin layer-line pattern during contraction provide further

good evidence that contractile force is produced by cross-bridges which attach to actin in the active muscle and undergo some form of tilting and pulling movement, as suggested previously²⁷. The experiments also demonstrate the usefulness of synchrotron radiation as a high-intensity X-ray source for time-resolved studies: it should also be possible to extend the scope of such studies considerably.

We thank Professor H. Stuhmann, Head of the EMBL Outstation, Hamburg, and other members of the EMBL staff for their support.

Order and intracellular location of the events involved in the maturation of a spliced tRNA

D. A. Melton, E. M. De Robertis & R. Cortese*

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Microinjected frog oocytes were used to analyse the RNA processing steps which lead to the appearance of a mature cytoplasmic tRNA^{tyr} molecule. The results show that removal of the intervening sequence from within a yeast tRNA^{tyr} precursor, excision of extra 3' and 5' nucleotides, addition of a 3'-terminal CCA and modification of at least seven ribonucleotides all occur in the nucleus before the tRNA^{tyr} is transported to the cytoplasm. Moreover, we find that the ribonucleotide modifications occur in a strict order which precisely correlates with the size alterations of the tRNA^{tyr} precursor.

THE transcript of most eukaryotic genes is an RNA precursor which must be processed post-transcriptionally to yield a functional gene product¹⁻³. In the case of transfer RNAs the RNA processing or maturation includes size alterations and base modifications of an RNA precursor as well as transport of the RNA from the nucleus to the cytoplasm (reviewed by Smith in ref. 4). Furthermore, in the light of the discovery of intervening sequences in some tRNA precursors⁵⁻⁹, it is now clear that tRNA maturation sometimes involves the removal or splicing of intervening RNA sequences. At present, the intracellular location of the precursors and mature tRNAs and the relative order of the various processing steps is virtually unknown for eukaryotic tRNAs. This article describes how and where in the cell the RNA transcript of a yeast tyrosine tRNA gene is processed into a mature cytoplasmic tRNA.

The DNA sequences of four of the eight tyrosine tRNA genes (tDNA^{tyr}) of the yeast *Saccharomyces cerevisiae* have been determined (ref. 5 and P. Phillipsen, J. R. Cameron and R. W. Davis, personal communication). These data have shown that the tRNA^{tyr} genes contain a 14 base-pair intervening sequence, adjacent to the anticodon, which is not present in the mature tRNA. Previous studies on the expression of this gene in microinjected frog oocytes showed that the tDNA^{tyr} is first transcribed as a precursor RNA which has an extension at the 5' end of the mature molecule and an intervening sequence, but lacks a 3'-terminal CCA¹². In this article we analyse the processing of

the tRNA^{tyr} precursor in detail, focusing on the intracellular location of the RNA processing events. We conclude that (1) tRNA precursors with immature ends (having 5' leader and 3' trailer sequences) are located only in the nucleus, (2) removal or splicing of the intervening sequence occurs in the nucleus or at the nuclear membrane and (3) size alterations and base modifications occur in a strict temporal order.

Expression of cloned tRNA genes in injected oocytes

Amphibian oocytes have been used extensively as a biological test system for the expression of purified mRNAs and more recently for cloned genes (reviewed in ref. 13). It has been shown that cloned DNAs are accurately transcribed following injection into the nucleus of intact *Xenopus* oocytes¹⁴⁻¹⁸ or after addition *in vitro* to oocyte nuclear extracts¹⁹⁻²². Correct processing of the RNA transcripts in this system is demonstrated by the fact that oocytes injected with a cloned tRNA gene synthesise a tRNA precursor and process it into a mature tRNA having the correct size, sequence and even some of the appropriate base modifications^{12,18}. Moreover, the transcripts from the injected genes are translated into proteins in some cases, for example, SV40 DNA and sea urchin histone DNA^{23,24,46}.

In using this 'living test tube' to study the transcription of cloned DNAs many copies (usually about 10⁸) of one gene are injected into each oocyte. Consequently, the unusual situation exists in which most of the cells' newly synthesised RNA is

* Present address: European Molecular Biology Laboratory, 6900 Heidelberg, FRG.

Fig. 1 Transcriptional products of $tDNA^{tyr}$ in injected oocytes. Oocytes were injected with $tDNA^{tyr}$ (plasmid pYTC (ref. 12), 5 ng per oocyte) and ^{32}P - α -GTP (10 mCi mol $^{-1}$), incubated for 6 h and the ^{32}P RNAs were extracted and electrophoresed in a 10% acrylamide gel as described¹⁸. The autoradiogram (left) shows the $tDNA^{tyr}$ precursors and mature $tRNA^{tyr}$ with their approximate lengths (± 4 bases). The structures of the precursors (right) were determined by comparing the RNA fingerprints (as in Fig. 4) with the DNA sequence as described in refs 5 and 12. The 5' leader is about 19 bases long, the intervening sequence is 14 bases long, the 3' trailer is 2 or 3 U, and the mature tRNA is 78 bases long. For the RNA sequences and a possible secondary structure of the precursors see ref. 12.

transcribed from just one type of gene: the injected template. When, for example, yeast $tDNA^{tyr}$ is injected into oocytes the transcripts from this gene, which include mature $tRNA^{tyr}$ and four $tRNA^{tyr}$ precursors, comprise up to 80% of the cells' newly synthesised RNA. This readily allows one to determine the structure of the tRNA precursors.

The intracellular location of the precursors and their processing enzymes can also be determined with this injection system²⁵. The *Xenopus* oocyte is such a large cell (~ 1.2 mm diameter) that its nucleus or germinal vesicle (~ 0.4 mm diameter) can be isolated by manual dissection. Thus, the newly synthesised RNAs present in the nucleus and cytoplasm can be analysed separately. Moreover, so many $tDNA$ transcripts are produced by one injected oocyte ($\sim 2,000$ d.p.m. of ^{32}P -labelled RNA h $^{-1}$) that these transcriptional products can be analysed using a single injected oocyte.

tRNA Precursors with 5' leader and 3' trailer sequences do not leave the nucleus

When oocytes are injected with $tDNA^{tyr}$ and radioactive ribonucleotide triphosphates five main RNA species are synthesised. The structures of the $tRNA^{tyr}$ precursors, determined by RNA fingerprinting techniques, are shown schematically in Fig. 1. Note that the three longest precursors (108, 104, and 97 bases) all contain extensions at the 5' and 3' termini of the tRNA and an intervening sequence in the coding region. By a stepwise removal of the 5' leader sequence these precursors are processed into a 92-base precursor which has a mature 5' end, retains the intervening sequence, and has a 3' CCA. Finally, the 14 base-pair intervening sequence is removed giving rise to mature $tRNA^{tyr}$.

The intracellular location of the $tDNA^{tyr}$ transcripts was determined by dissecting oocytes which had been previously injected with $tDNA^{tyr}$ and [α - ^{32}P]GTP. In these experiments the RNAs present in the nucleus and in the cytoplasm were determined by analysing single oocytes. The results show a partitioning of the transcripts between the nucleus and cytoplasm (Fig. 2). All of the $tRNA^{tyr}$ precursors which contain 5' leader and 3' trailer sequences are found exclusively in the nucleus. The 92-base precursor which contains the intervening sequence, but has mature 5' and 3' termini, is found in both the nucleus and cytoplasm. The mature $tRNA^{tyr}$ (78 bases) is found predominantly, if not exclusively, in the cytoplasm.

After 2.5 h of $tDNA^{tyr}$ transcription most of the transcripts are still in the nucleus and little if any mature $tRNA^{tyr}$ has appeared (Fig. 2). By 6 h some mature $tRNA^{tyr}$ is detected in the cytoplasm and the 92-base precursor is the most prevalent transcript. By 24 h more mature $tRNA^{tyr}$ has accumulated in the cytoplasm, but the 92-base precursor is still the major transcriptional product.

From these results we conclude that tRNA precursors with extra tracts of RNA at their termini are localised in the nucleus. One trivial explanation for this observation is that the larger precursors are rapidly processed and/or degraded upon entering the cytoplasm. This possibility has been rendered improbable by experiments in which the 108-, 104- and 97-base precursors were injected directly into the oocyte cytoplasm and found to be stable. The nuclear segregation found for these $tRNA^{tyr}$ precursors has also been observed following micro-injection of other tRNA genes, including nematode leucine

Fig. 2 Intracellular location of $tDNA^{tyr}$ transcripts. Single oocytes which had been previously injected with $tDNA^{tyr}$ and [α - ^{32}P]GTP were manually dissected⁴² after incubation at 19 °C for 2.5, 6 and 24 h and the RNAs present in each individual nucleus and cytoplasm were electrophoresed in 10% acrylamide gels¹⁸. The autoradiograms of these gels (like that in Fig. 1) were traced with a Joyce-Lobel densitometer. The tracings from three representative oocytes are shown. Nuc, nucleus; Cyt, cytoplasm.

Fig. 3 Splicing of the intervening sequence is associated with the nucleus. Radioactive 92-base $tRNA^{tyr}$ precursor from injected oocytes was purified by extraction from acrylamide gels²⁵. This ^{32}P -labelled precursor, the substrate for the splicing enzyme(s), was injected into enucleated oocytes⁴³, the cytoplasm, or the nucleus of intact oocytes using approximately 5,000 d.p.m. of ^{32}P -labelled RNA per oocyte. After an 18-h incubation the injected oocytes were homogenised and the ^{32}P RNAs were extracted and electrophoresed in a 10% acrylamide gel. Two uninjected markers, for the 92-base precursor and the spliced $tRNA^{tyr}$, were electrophoresed in adjacent tracks. The densitometer tracings of this acrylamide gel are shown.

$tDNA^{25}$ and yeast serine $tDNA$ (J. Broach, R. Cortese and D. A. Melton, unpublished data). In all these cases, the common feature of the $tRNA$ precursors which are partitioned in the nucleus is that they have unfinished termini, that is, they have 5' leader and 3' trailer sequences.

Splicing of the intervening sequence occurs in the nucleus

A splicing activity has been isolated from nuclear preparations⁶ and from a cytoplasmic ribosomal wash in yeast⁸. However, the difficulties in obtaining pure preparations of nuclei and cytoplasmic fractions have led to uncertainties about the location of the splicing enzymes. Our results based on the dissection of injected oocytes (Fig. 2) show a similar ambiguity in that the 92-base precursor, the substrate for the splicing enzyme, is found in both the nucleus and cytoplasm whereas the mature $tRNA^{tyr}$ is found mostly in the cytoplasm. The two obvious possibilities for the removal of the intervening sequence are that

(1) the 92-base precursor is transported to the cytoplasm and then the intervening sequence is removed to give mature $tRNA^{tyr}$ or (2) the splicing occurs in the nucleus and the mature $tRNA^{tyr}$ is then quickly (or even as a consequence) transported to the cytoplasm.

We have tested the location of the splicing enzyme(s) in intact cells by injecting ^{32}P -labelled 92-base precursor RNA into the nucleus, the cytoplasm, and into enucleated oocytes. Figure 3 shows that a significant amount of the 92-base precursor is spliced only when the RNA is injected into the nucleus. This strongly suggests that the last step in tailoring the size of the precursor, the excision of the intervening sequence and subsequent ligation of the two $tRNA$ halves, is a nuclear event. Therefore, the splicing enzyme or enzyme complex might be in the nucleoplasm or located at the nuclear membrane. This conclusion is not affected by the problems posed by the biochemical purification of nuclei.

The splicing step is inefficient in injected oocytes: even after 6 d of $tDNA^{tyr}$ transcription only 30% of all the transcripts are spliced into mature $tRNA^{tyr}$ (ref. 12 and Fig. 2). The nuclear location of the splicing enzyme(s) could explain this inefficiency. Once the 92-base precursor enters the cytoplasm it is probably no longer accessible to the splicing enzyme(s). The 'leakage' of the 92-base precursor into the cytoplasm which we observe may result from the fact that the oocyte is overloaded with the transcripts of a single gene. One would not expect this to occur in normal yeast cells.

Post-transcriptional addition of CCA

All transfer RNAs have the sequence CCA at their 3' end, the attachment site for the amino acid. These three bases are not encoded in the yeast $tDNA^{tyr}$ and must therefore be added post-transcriptionally⁵.

The results presented in Fig. 4 show that the CCA is not present on the 104-base precursor. Analysis of the 97-base precursor (not shown) reveals that it has the same 3' terminus as the 104-base precursor, the CCA still being absent. By the 92-base precursor stage all of the molecules have a 3' CCA (Fig. 4f).

The presence of the CCA on the nuclear 92-base precursor suggests that these bases are added to the newly synthesised RNA in the nucleus. However, it seemed likely that the CCA-adding enzyme ($tRNA$ nucleotidyl transferase) would also be found in the cytoplasm because it is known that the 3' CCAs of $tRNAs$ are constantly removed and replaced or repaired in the cell^{26,27}. This was tested directly by injecting deadenylated $tRNA$ into different cell compartments. Deadenylated $tRNA$, a substrate for $tRNA$ nucleotidyl transferase, was prepared by chemically removing the 3'-terminal A residue from purified $tRNA^{tyr}$ (ref. 28). The results in Fig. 5 show that a 3'-terminal A residue can be added to deadenylated $tRNA^{tyr}$ in the cytoplasm as well as in the nucleus. Taken together with the results shown in Fig. 4, this shows that the enzyme $tRNA$ nucleotidyl transferase is present in both the nucleus and cytoplasm of the cell.

The experiments described so far suggest the following order for the size alterations of the $tRNA^{tyr}$ precursor: (1) stepwise removal of the 5' leader and 3' trailer sequences, (2) addition of a 3'-terminal CCA and (3) splicing of the intervening sequence. All of these processing events occur in the cell nucleus. In addition to these processing steps, the maturation of a $tRNA$ molecule involves modification of specific ribonucleotides. The relationship between the size alterations and base modifications of the $tRNA^{tyr}$ precursors is described below.

Ribonucleotide modifications occur in an obligatory order

The intracellular site at which the ribonucleotides are modified was examined by analysing the RNA fingerprints of the nuclear and cytoplasmic $tRNA^{tyr}$ precursors. The T_1 ribonuclease fingerprints of the nuclear 104-base, nuclear 92-base and cytoplasmic 92-base precursors are shown in Fig. 4. The minor bases

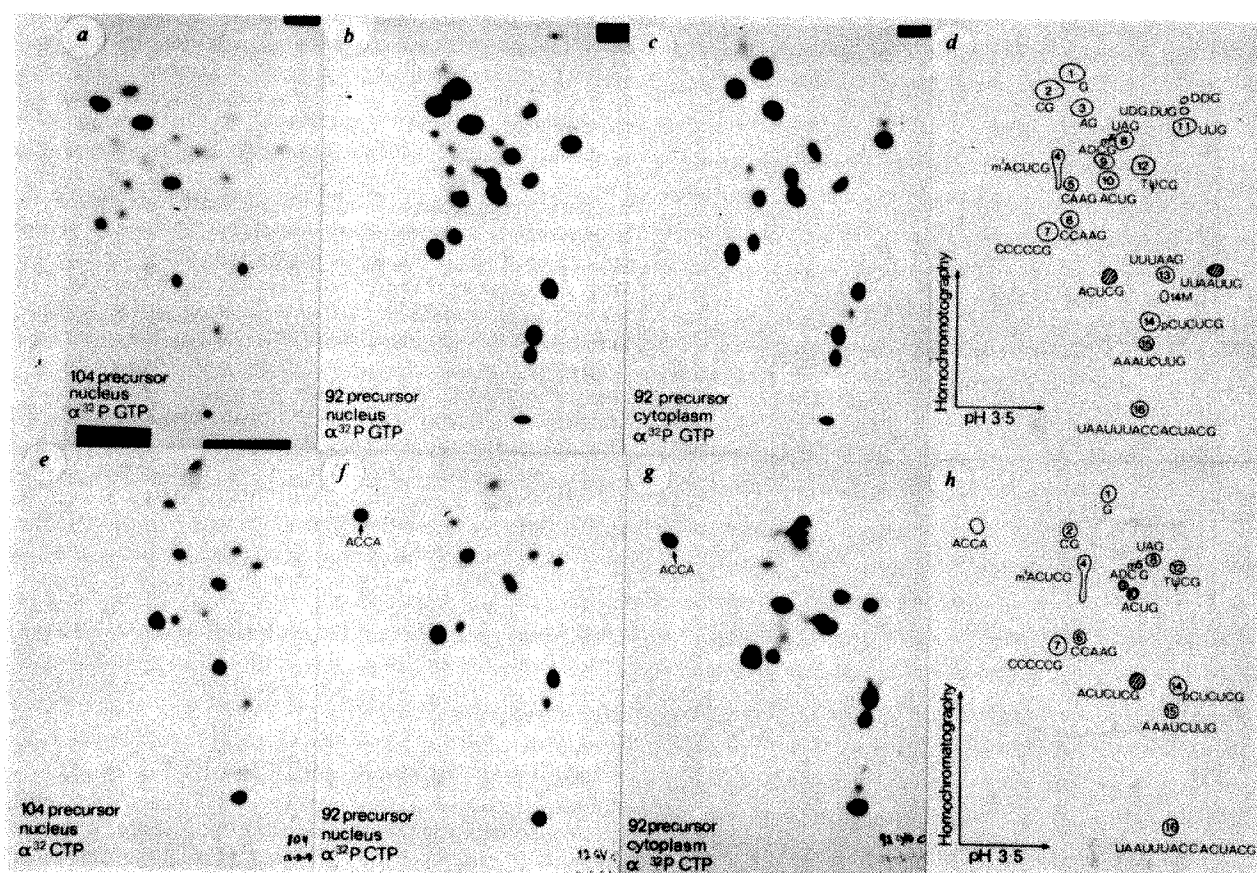

Fig. 4 RNA fingerprints of tRNA^{tyr} precursors synthesised in injected oocytes. ³²P precursor RNAs were isolated either from the nucleus or the cytoplasm of oocytes 5 h after injection with tDNA^{tyr} and [α-³²P]GTP (a–d) or [α-³²P]CTP (e–h). Following digestion with ribonuclease T₁ the oligonucleotides were separated in one dimension on cellulose-acetate at pH 3.5 and in the second dimension by homochromatography on DEAE-cellulose thin layer plates⁴⁴. Some background of small oligonucleotides from endogenous oocyte transcripts is apparent in the upper part of panels a and b. This is because the RNA bands analysed were relatively weak and the fingerprints had to be exposed for long periods. The diagrams at the right indicate the composition of the oligonucleotides; hatched spots are oligonucleotides unique to the 104-base precursor. For the numbering of the T₁ oligonucleotides and their position within the tRNA^{tyr} precursor see refs 5 and 12. Note the 3'-terminal CCA is present in the 92-base precursors (f, g), but absent in the 104-base precursor (e). Some base modifications affect the mobility of certain oligonucleotides, for example D in oligonucleotide 9, as discussed in the text.

present in the precursors were analysed by elution of the T₁ oligonucleotides, hydrolysis with alkali and thin layer chromatography²⁹. Table 1 summarises the results of this type of nearest neighbour analysis for some selected T₁ oligonucleotides, and shows that most of the base modifications analysed, including 5-methyl-cytosine (m⁵C), 1-methyladenosine (m¹A), pseudouridine (Ψ), and dihydrouridine (D), occur in the nucleus. The only modification found to be exclusively cytoplasmic is a G modification in T₁ oligonucleotide 14. This uncharacterised modification (see Table 1) causes the appearance of a new spot in the RNA fingerprint of the cytoplasmic 92-base precursor (see Fig. 4c, oligonucleotide 14M). It should be noted that although this nucleotide is not normally modified in yeast, all the other modifications described in Table 1 are normally present in yeast tRNA^{tyr}.

Analysis of the RNA fingerprints of the various tRNA^{tyr} precursors (as in Fig. 4) also showed that base modifications occur in an obligatory order which is strictly correlated with the size alterations of the tRNA precursors. Some modifications are present on precursors which have 5' leader and 3' trailer sequences while others do not occur until these sequences are removed (Table 1).

The correlation between the size reduction and base modification of the precursors is easily demonstrated in the cases where the base modifications cause a change in the mobility of a T₁ oligonucleotide. For example, oligonucleotide 9, which has the sequence ADm⁵CG, can be resolved from oligonucleotide 10, ACUG, only when the dihydrouridine (D) is present. In the 104-base precursor the two oligonucleotides, 9 and 10, overlap

(Fig. 4a) whereas in the 92-base precursor, which contains D in oligonucleotide 9, the two spots are separated in the fingerprint (compare Fig. 4a with 4b and c). This particular modification, U→D, is observed only in precursors which have had the 5' leader removed and the 3' CCA added. Other modifications, as indicated in Table 1, are found on precursors containing 5' leader and 3' trailer sequences. In the case of oligonucleotide 4, m¹ACUCG, the methylation of the adenosine causes an increased mobility in the second dimension of the fingerprint analysis. This nucleotide is already completely modified to m¹A at the 104-base precursor stage (Fig. 4e).

Perhaps the most striking example of the order in tRNA processing is provided by the case of two pseudouridine (Ψ) modifications. In the 104-base precursor there is a Ψ in the TΨC loop (oligonucleotide 12), but the Ψ which will eventually appear in the anticodon stem (oligonucleotide 15) is absent. Once the 5' leader sequence is removed and the 3' CCA added, the U in the anticodon stem of the 92-base precursor is completely modified to Ψ (Table 1). It should be noted that only a selected subset of the possible base modifications was analysed here. Other base modifications may well occur.

We therefore observe an apparently invariant order in the processing of the tRNA^{tyr} precursors. The order of events is said to be invariant in that we do not find, for example, precursors which have had the intervening sequence removed but still retain a 5' leader sequence. Nor, for example, are certain nucleotides modified in precursors which still have a 5' leader. Conventionally, the maturation of tRNA precursors is divided into two separate processes: size reduction and base

Fig. 5 Addition of a 3'-terminal A residue to transfer RNA in injected oocytes. [α - 32 P]ATP (10 mCi ml $^{-1}$) was injected with (+) or without (–) deadenylated tRNA^{tyr} (25 ng per oocyte) into either the nucleus (Nuc) or the cytoplasm (Cyt) of intact oocytes and into enucleated oocytes (ENUC). After an incubation of 1.5 h the RNA was extracted and electrophoresed in a 10% acrylamide gel as in Fig. 1. Pure tRNA^{tyr} (provided by M. Olson) had the 3'-terminal A removed by periodate treatment²⁸. Pure tRNA^{tyr} which had not been treated with periodate was injected into oocytes with [α - 32 P]ATP as the control (cont.).

modification. The results presented here show that these processes are in fact intimately related and proceed in concert with each other.

Discussion

A plausible scheme for the steps involved in the biosynthesis of yeast tRNA^{tyr} as observed in injected oocytes is shown in Fig. 6. Perhaps the most striking aspect of this pathway is that almost all of the RNA processing occurs in the nucleus. From the nuclear location of the tRNA^{tyr} precursors one can infer that certain maturation enzymes must be located in the nucleus. These include the enzymes that synthesise 1-methyl-adenosine, 5-methyl-cytosine, pseudouridine, and dihydrouridine (Table 1). Furthermore, experimental evidence has been presented to show that the removal of the 5' leader sequence, splicing, and addition of the 3' CCA all occur in the nucleus (Figs 3, 5, ref. 25). Earlier studies based on the biochemical fractionation of nuclei and cytoplasm indicated that tRNA precursors are found and processed in the cytoplasm^{26,30–33}. With different methods, namely the manual isolation of the oocyte's large nucleus and the direct injection of radioactive RNAs into various cell compartments, the results reported here and those of Lönn³⁴ support the conclusion that almost all of the maturation of tRNA precursors occurs in the nucleus.

Table 1 Order and intracellular location of base modifications

Ribonucleotide modification	T ₁ oligonucleotide	Precursor (bases)		
		104 nucleus	92 nucleus	92 cytoplasm
m ¹ A	4 (TΨC loop)	+	+	+
m ⁵ C	9 (variable loop)	+	+	+
Ψ	12 (TΨC loop)	+	+	+
	15 (anticodon stem)	–	+	+
D	9 (variable loop)	–	+	+
	11 (D loop)	–	+	+
G*	14M (aa stem)	–	–	+

The 104-base and 92-base tRNA^{tyr} precursors were isolated from either the nucleus or cytoplasm of oocytes which had been injected with tDNA^{tyr} and [α - 32 P]GTP or [α - 32 P]CTP. The modified bases present in selected T₁ oligonucleotides were characterised by pancreatic RNase digestion or alkali hydrolysis followed by cellulose thin layer chromatography in isopropanol: H₂O:HCl (70:15:15 v/v)⁴⁵ or paper electrophoresis at pH 3.5 (ref. 44). The T₁ oligonucleotides are numbered as in Fig. 4. Note that most of the modifications occur in the nucleus (except for G*) and that some modifications only occur after the termini of the precursor have been matured. m¹A, 1-methyladenosine; m⁵C, 5-methylcytosine; Ψ, pseudouridine; D, dihydrouridine; G* is an uncharacterised G modification whose migration by paper electrophoresis is consistent with it being Gm (2-O-methylguanosine) or some other modification that renders G resistant to ribonuclease T₁ cleavage.

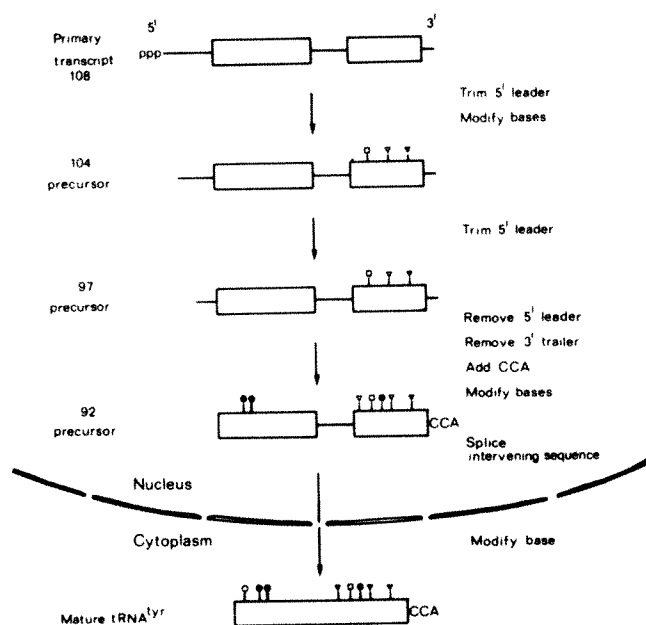

Fig. 6 RNA processing of tRNA^{tyr} precursors into mature tRNA^{tyr} in injected oocytes. The primary transcript of tDNA^{tyr} is a precursor 108(±4) nucleotides in length with a 5' leader, intervening sequence and 3' trailer (as in Fig. 1). This is the only precursor which has a 5'-terminal triphosphate¹². The 5' leader is removed in three stages, the last of which is accompanied by excision of the 3' trailer and addition of the 3' CCA. The position and type of the base modifications are indicated as well as the stage at which they appear. The modified bases in the 108-base and 97-base precursors have not been analysed. Therefore some of the modified bases shown to be newly added at the 92-base precursor stage may be present on the 97-base precursor, but these are definitely absent in the 104-base precursor (Table 1). Note that only some base modifications have been analysed; others may well occur. The 92-base precursor which enters the cytoplasm (Fig. 2) is not shown because our results suggest that the cytoplasmic 92-base precursor is not processed to mature tRNA (see text). □, 5-methyl-cytosine; ▽, pseudouridine; ▼, 1-methyladenosine; ●, dihydrouridine; ○, G*, an uncharacterised G modification.

Superimposed on the spatial order of the tRNA processing we have observed a correlation between the size changes and base modifications of the tRNA precursors. Previous studies have suggested that the length reduction of tRNA precursors occurs in a precise order^{4,35-39}, but little work has been done on its connection to base modification. Two notable exceptions from studies on bacterial tRNAs are the demonstration that a Gm modification is absent in a bacteriophage T₄ tRNA precursor⁴⁰ and *in vitro* studies on the effect of pseudouridine modifications on *E. coli* tRNA^{tyr} cleavage by RNase P (ref. 41). The obligatory order observed for the yeast tRNA^{tyr} base modifications can be explained by assuming that each of the tRNA^{tyr} precursors is a substrate for a particular subset of maturation enzymes. For example, the presence of a 5' leader sequence could introduce order into the maturation process by altering the tertiary structure of the precursor. Some maturation enzymes might recognise precursors with a 5' leader while others would accept the precursor as a substrate only after the 5' leader has been removed. The specific sequence in which the bases of the 104-base precursor and then the 92-base precursor are modified provides some support for this suggestion (Fig. 6). The possibility remains that the intervening sequence might similarly order an additional round of base modifications, but this was not tested in the present study.

In conclusion, it is not immediately obvious why a gene product as apparently simple as a tRNA is synthesised via such a complicated processing scheme. One hint, however, comes from our previous observation¹² that different genetic loci of the same tRNA gene are transcribed into RNA precursors all of which have a 5' leader, though the length and sequence of this extra segment varies in each case. The fact that the 5' leader is present in the case of the four yeast tyrosine tDNAs and the two yeast serine tDNAs examined suggests that it may have some biological function (ref. 12 and J. Broach, R. Cortese and D. A. Melton, unpublished data). Our studies implicate the 5' leader as having a possible role in two related aspects of tRNA processing: the ordering of base modifications and the nuclear segregation of tRNA precursors. Together these results suggest that a possible function for extra terminal sequences on tRNA precursors is to ensure that normally only a mature tRNA is presented to the cytoplasm for participation in protein synthesis.

We thank J. B. Gurdon, R. Harland and J. D. Smith for discussions, P. Black for technical assistance, and Barbara Rodbard for help in preparing the manuscript. J. B. Gurdon, B. J. Meyer, and J. D. Smith read the manuscript carefully and we are grateful for their suggestions.

Recent IUE observations reveal striking differences in the UV spectra of two symbiotic stars, R Aqr and RW Hya. RW Hya is found to be an unexpectedly intense source of UV radiation. The measurements reported here demonstrate the presence of a hot component in each star, supporting the view that each is a binary system with a luminous red primary and a hot, sub-luminous companion. In one case, the hot companion manifests itself by exciting a compact nebulosity; in the other case we believe that the continuous spectrum of the hot star is directly detected, while the continuum of nebulosity excited by the hot star is detected at longer wavelengths.

Our observations were made in the wavelength range 1,200-3,200 Å. The UV continuum found in the spectrum of R Aqr and shown in Fig. 1a is most easily interpreted as emission from a dense and compact nebula, which must be ionised by UV photons from a hot secondary. From visible light spectra, R Aqr is classified¹ as M7+pec. The continuum seen in Fig. 1a is ascribed to Balmer emission that arises from recombination radiation of hydrogen atoms. The nebula also produces both permitted and semi-forbidden lines of various ions. Observations in the IUE long-wavelength range (1,900-3,200 Å) also show the forbidden line of O II at λ 2,470 Å and a strong emission feature at λ 2,328 Å that must represent a blend of λ 2,321 Å [O III] and λλ 2,325, 2,327, 2,328 Å C II]. The most prominent emission lines include C III], C IV, Si II, Si III] and Si IV (Fig. 1a). Lower intensity features are not indicated since blends due to the ~6 Å spectral resolution make some identifications of weak lines ambiguous. The λλ 1,808 and 1,806 Å lines of Si II, for example, most likely correspond to the broad emission feature evident in Fig. 1a.

The relatively low excitation spectrum of the nebula indicates that the nebula is excited by a star (with effective temperature $T \geq 50,000$ K) that resembles a white dwarf or the central star of a planetary nebula. Only such a star can produce enough

ionising photons as required by the present measurements ($\sim 10^{42} \text{ s}^{-1}$) and yet be sufficiently faint (given the estimated distance of $\sim 260 \text{ pc}$) (ref. 1) so that the stellar continuum does not dominate the UV spectrum of R Aqr. Our computations are based on an estimated colour excess, $E(B-V) \approx 0.05 \text{ mag}$, corresponding to an interstellar extinction at wavelength $1,550 \text{ \AA}$, $A_\lambda \approx 0.37 \text{ mag}$.

The feature at $\sim 1,250 \text{ \AA}$ is indicated in Fig. 1 as composite emission of S II and N V. However, presumably it is dominated by S II as the relatively low excitation of this ion is consistent with the nebular temperatures deduced from the oxygen and carbon line intensities. Our low spectral resolution observations cannot positively differentiate one ion species from another in this feature. However, we find that a compact dense nebula of $n_e \sim 10^6 \text{ cm}^{-3}$ and temperature $T \geq 15,000 \text{ K}$ suggests that it is due mainly to S II rather than the higher excitation emission line of N V. Also, the UV emission observed is not adequately explained by a hot chromosphere in the M giant primary, because the densities required to produce other emission lines observed ($n_e \sim 10^7\text{--}10^8 \text{ cm}^{-3}$) at typical chromospheric temperatures $T \leq 10,000 \text{ K}$ at these densities would be inconsistent with the presence of [O III] emission at $2,321 \text{ \AA}$ that is observed in the IUE long-wavelength range.

RW Hya is classified gM2 + pec and varies between 10 and 11 visual magnitudes. Attributing the visual flux to the red giant primary, we estimate the distance to the system as $\sim 1 \text{ kpc}$. Although the presence of hot companions in symbiotic stars has been suspected, the intensity of UV radiation from RW Hya is surprising. The resonance lines of the C IV ion at wavelengths $1,548, 1,550 \text{ \AA}$ are so bright that they saturate in a single pixel in an exposure time of 30 s with the short wavelength, low dispersion IUE spectrometer. The star appears to be essentially unreddened and is notable for the strong UV continuum that (Fig. 1b) rises towards short wavelengths. The distance of $\sim 1 \text{ kpc}$ deduced for RW Hya was obtained from the interstellar absorption of Ly α that produces an absorption equivalent width $w_{\lambda 1,216} \sim 1.5 \text{ \AA}$. The corresponding hydrogen column density in our line of sight $N_{\text{H I}} \sim 6.4 \times 10^{18} \text{ cm}^{-2}$ corresponds to an extinction $E(B-V) \approx 0.001$. This small absorption value is attributed to the height of RW Hya above the galactic plane ($l = 316^\circ$, $b = +36.5^\circ$) which places the star at a distance $\sim 700 \text{ pc}$ above the plane of the galaxy.

The continuum observed in RW Hya fits a Rayleigh-Jeans approximation to a black-body law that corresponds to an effective temperature $T \geq 10^5 \text{ K}$, with a peak that probably occurs well below the wavelength range of IUE near 500 \AA . Model atmospheres for hot white dwarfs show that in the UV range over which we observe a strong continuum, the thermal emission of such stars is approximated closely by that of a black body⁵. This must represent the emission of a subluminescent star, brighter and hotter than the companion of R Aqr. The continuum of the hot component in RW Hya, if it continues to follow the Rayleigh-Jeans law, must fall well below the continuum that we actually observe above $1,900 \text{ \AA}$ with the long wavelength, low dispersion IUE spectrograph. The long wavelength UV continuum, much too bright to arise in the M primary, is ascribed to nebulosity excited by the secondary star. Although both permitted and semi-forbidden emission lines are found, we have not identified any forbidden line in the UV spectrum of RW Hya, suggesting that the nebulosity in this star may be more dense (and perhaps smaller) than that in the R Aqr system.

The physical conditions that are responsible for the UV emission from these two symbiotic stars are notably different. The relatively low excitation emission observed in the line spectrum of R Aqr is indicative of a nebula photoionised by the hot star in the system. The prevailing density in the nebula, as deduced from the carbon and forbidden oxygen line strengths, must be roughly 10^6 cm^{-3} , while the scale of the nebula is $\leq 10^{15} \text{ cm}$ and the electron temperature is $\approx 15,000 \text{ K}$. The electron density and temperature of the nebula in which the primary and secondary are embedded was obtained from the

Fig. 1 UV spectra of the symbiotic stars R Aqr (a) and RW Hya (b) obtained with the short wavelength, low dispersion spectrograph of the IUE observatory satellite on 29 July 1979 and 1 September 1979 respectively. Note in b that the resonance lines of C IV at $1,548 \text{ \AA}$ and $1,550 \text{ \AA}$ are off scale and that the pronounced continuum rises towards shorter wavelengths, and that Ly α is in absorption. The spectra have been corrected for the absolute response of the instrument, but not for interstellar reddening, which affects the R Aqr spectrum. The Ly α emission line observed in R Aqr represents combined geocoronal and stellar emission.

relation and parameters of Osterbrock² for planetary nebulae, where we have used appropriate cosmic abundances for oxygen and carbon. Here the observed flux for a particular emission line is assumed to be proportional to $n_e^2 L^3$ for a given temperature, distance and cosmic abundance. Note that the scale size L of the nebula is comparable to the diameter of the hot star's orbit, if the orbital period is $\sim 27 \text{ yr}$ (ref. 3).

In contrast, the lack of significant emission in the $2,321 \text{ \AA}$ line of [O III], and the strong permitted line emissions, suggest that the nebulosity in RW Hya is much denser, $\sim 10^9 \text{ cm}^{-3}$, and hotter, $T_e = 20,000 \text{ K}$. The strong permitted line emissions, such as those due to C IV and O I, may be the result of mechanical heating of the gas as the result of tidal interaction between the extended envelope of the red giant primary and the compact companion. Mass accretion onto the surface of the companion can result in thermal heating of the accreting surface⁶. The He II line at $1,640 \text{ \AA}$ observed in both symbiotic stars is observed to be far more intense in RW Hya than R Aqr, confirming that RW Hya is a higher excitation source. The relatively weaker He II $1,640 \text{ \AA}$ emission observed in the spectrum of R Aqr probably reflects the lower ionisation of a nebula that is excited by a relatively cooler companion star. The presence of this high temperature line is possibly explained by emission arising in very

close proximity to the hot component with coronal temperatures.

Mass transfer may be a significant energy source in RW Hya and may be related to the intense UV emission and to the higher apparent effective temperature of its companion star, as compared with R Aqr. As in other types of binary systems, a distinguishing characteristic among individual symbiotic stars may be the degree of mass transfer onto the compact star. This is supported by IUE observations of CH Cyg, which reveal an UV continuum ascribed to mass transfer from the M6–M7 III primary on to the hot subluminescent secondary which results in an optically thick UV-emitting corona around the secondary⁶, a model supported by optical spectra as well. Given the energetics of the accretion process in white dwarfs, luminosities of $\sim 10^{36}$ erg s⁻¹ in the X-ray regime (1–4 keV) seem possible⁴. Accordingly, RW Hya may be a detectable source with the imaging proportional counter on the HEAO 2 (Einstein) observatory.

We thank the Project Scientist, Observatory Administrator, Resident Astronomers and the staff of IUE at NASA Goddard Space Flight Center for their support. Full details of this work will be published elsewhere.

A model for ball lightning

G. C. Dijkhuis

Zeldenrust College, Terneuzen, The Netherlands

An eyewitness sees ball lightning as a luminous sphere in regions of thunderstorm activity. There are many reports of ball lightning forming after a lightning discharge, existing for several seconds, and terminating suddenly and silently, or exploding with or without material damage^{1,2}. Jennison³ has described ball lightning observed at close range inside a commercial aircraft shortly after a lightning discharge. As it drifted down the aisle of the passenger cabin, this ball lightning exhibited: (1) perfect equilibrium in a perfectly spherical shape with diameter 22 ± 2 cm; (2) 5–10 W of optical radiation in blue-white light, but no heat radiation; and (3) an optically thick surface of almost solid appearance, devoid of polar or toroidal structure, but with some limb-darkening. It seems unreasonable to dismiss Jennison's ball lightning as an optical illusion⁴ (afterimage of the eye's retina). A physical explanation in terms of a microwave cavity⁵, a d.c. glow discharge⁶, chemical reactions⁷, nuclear reactions⁸ or annihilation of antimatter⁹ runs into difficulties since the all-metal airplane structure would act effectively as an air-tight Faraday cage. A plethora of excited atoms and molecules, and electromagnetic waves ranging from radio frequencies to X rays are produced in the channel of a lightning discharge, but only electric charge itself can enter the interior of an all-metal airplane without difficulty. Here a new model is presented which explains ball lightning in terms of electric charge.

Charge transfer through ionised air generally obeys Ohm's law $\mathbf{j} = \sigma \mathbf{E}$, where \mathbf{j} stands for current density and \mathbf{E} for electric field. The scalar factor σ is the electrical conductivity. The discharge current magnetises the ionised region where it passes. This magnetisation is dissipated into heat on a time scale known as the magnetic diffusion time τ . Magnetic field lines are 'frozen into' the plasma for a time span¹⁰:

$$\tau = \mu \sigma L^2 \quad (1)$$

where μ is magnetic permeability, σ is electrical conductivity and L is a typical length scale of the ionised region. From his measurements of the emission line profile of H α , Uman¹¹ has calculated a conductivity of 1.8×10^{14} S m⁻¹ during the high-temperature phase of a lightning discharge. With vacuum permeability $\mu_0 = 4\pi \times 10^{-7}$ N/A², and with 10 cm diameter for the lightning channel, equation (1) yields a magnetic diffusion time of 2.3×10^{-4} s. This short time scale is clearly incompatible with observed ball lightning lifetimes, but it can easily account for instantaneous disappearance of a magnetised plasma sphere in air.

Equation (1) offers two ways of suppressing magnetic dissipation by ohmic losses in the plasma. First, the magnetic permeability μ could be larger than the vacuum permeability μ_0 , as in ferromagnetic materials. Below the Curie temperature, a ferromagnet has a permanent magnetic field, corresponding to $\mu = \infty$ in equation (1). Second, the electrical conductivity σ could be higher than in the lightning channel. Infinite conductivity is found in superconducting materials below the transition temperature, where electrical currents persist indefinitely. Uman's lightning channel conductivity of 1.8×10^{14} S m⁻¹ holds good for laminar plasma motion only. Plasma turbulence will enhance charge transfer by translations of charged fluid parcels, and rotations of charged fluid parcels will generate a magnetic field. Our first hypothesis is that turbulence in the ball lightning plasma enhances charge transfer to the point that charged vortices transport electricity the way electrons do in a superconductor. By this hypothesis, individual plasma vortices have a strong tendency to travel with the same momentum and spin with aligned axes; as such they behave macroscopically the way bosons do on the atomic level.

Feynman¹² has shown that a fluid consisting of charged bosons has potential energy of the form $\nabla^2 \rho^{1/2} / \rho^{1/2}$, where ρ stands for the charge density, or, by virtue of Coulomb forces between electrons and ions, for mass density. This potential energy is zero for a uniform distribution ρ is constant (as in solids), but it can be positive as well as negative in a density-stratified plasma with non-uniform ρ . Correcting the sign of Feynman's expression we write $U = -C \nabla^2 \rho^{1/2} / \rho^{1/2}$ ($C > 0$) for the potential energy U , corresponding to interaction between plasma vortices with a force field $-\nabla U = \nabla C \nabla^2 \rho^{1/2} / \rho^{1/2}$. In hydrostatic equilibrium this force field is balanced by pressure forces only, hence¹⁶:

$$0 = \frac{-1}{\rho} \nabla p + \nabla C \frac{\nabla^2 \rho^{1/2}}{\rho^{1/2}} \quad (2)$$

where the total pressure p includes kinetic pressure from electrons and ions, and turbulent pressure from plasma vortices.

Fig. 1 Three density profiles of isobaric ball lightning models with different binding energies. Inset, square well potential energy of isobaric density profiles.

Each plasma vortex exerts centrifugal forces on its neighbours, which dominate over kinetic pressure when plasma circulation inside the vortex exceeds the local speed of sound. Such supersonic circulation causes density gradients on the length scale of one plasma vortex, resulting in a sponge-like structure of tenuous vortex cores nested in dense ambient plasma.

Collective motions of electrons and ions on length scales smaller than one Debye length are dissipated by Landau damping¹⁵, and local deviations from charge neutrality are screened out on length scales larger than one Debye length¹⁵. Thus the sizes of plasma vortices behaving as charged bosons apparently lies around one Debye length. Since Debye length scales as $T^{1/2}/n^{1/2}$ with temperature T and electron density n , a hot and tenuous region of the ball lightning plasma has larger vortices with more electrons and ions than a cooler and more dense region. High-pressure arc plasmas typically have a Debye length around 10^{-6} cm, which may serve as a lower limit on the size of plasma vortices in our ball lightning model.

The virial theorem⁶ yields $3pV$ as an upper limit on the energy content of a plasmoid with pressure p and volume V . Confinement by atmospheric pressure only, results in a maximum energy content of $\sim 10^3$ J, which is several orders of magnitude below ball lightning energies reported elsewhere^{1,8}. Some ball lightning theories avoid this difficulty by postulating a continuous energy input through radiowaves⁵ or d.c. currents⁹. Our boson model for plasma turbulence lifts the virial constraint on maximum energy content with negative potential energy from interaction between plasma vortices. With internal confinement forces as in equation (2), hydrostatic equilibrium of the ball lightning plasma demands internal pressures above 1 atm. The energy $\int p dV$ stored in the pressure distribution includes thermal energy from electrons and ions, and turbulent energy from vortex motion.

Equation (2) is nonlinear except in the isobaric case where p is constant. For spherical symmetry, the non-singular isobaric solution with negative potential energy $U = -\kappa^2 C$ is^{13,16}:

$$\rho^{1/2} = \rho_C^{1/2} \frac{\sinh(\kappa r)}{\kappa r} \quad (3)$$

where ρ_C denotes the central density of the plasma sphere, and $1/\kappa$ is a length scale. In the limit $\kappa \rightarrow 0$, equation (3) represents a uniform and isothermal plasma sphere without potential energy. Density stratification appears as κ increases from zero, giving progressively more negative potential energies $-\kappa^2 C$, and lower central densities ρ_C . A complementary stratification in temperature maintains isobaric conditions in the gas. Thus equation (3) represents a plasma sphere with a hot and tenuous central region surrounded by a cooler and more dense 'gas blanket'.

For a ball lightning floating in air, the mean density $\bar{\rho}$ cannot be far from atmospheric density, 1.3 kg m^{-3} . On squaring and integrating equation (3) over the volume of a sphere with radius R , the mean density comes out as $\bar{\rho} = 3\rho_C \{[\sinh(\kappa R) \cosh(\kappa R) - \kappa R]/2\kappa^3 R^3\}$. Using $\sinh(\kappa R) = \cosh(\kappa R) = \frac{1}{2}e^{\kappa R} \gg \kappa R$ for $\kappa R \gg 1$, the ratio of central density ρ_C and surface density ρ_s to mean density $\bar{\rho}$ is approximately:

$$\frac{\rho_C}{\bar{\rho}} \approx \frac{8}{3} \kappa^3 R^3 e^{-2\kappa R}; \quad \frac{\rho_s}{\bar{\rho}} \approx \frac{2}{3} \kappa R \quad (4)$$

which hold to better than 1% for $\kappa R \geq 5$. Density profiles relative to mean density are sketched in Fig. 1 for $\kappa R = 5, 10$ and 20. At the centre $r = 0$, all profiles are horizontal, as required for a physically acceptable solution. By assumption, the whole interior region $r < R$ is isobaric and therefore force-free. Binding forces from negative potential energy only appear as stresses on the surface $r = R$, where the density abruptly returns to atmospheric conditions over a small distance Δr . In the limit $\Delta r \rightarrow 0$, this discontinuity in ρ results in surface stresses tending to infinity as $1/(\Delta r)^3$, by equation (2). A pressure discontinuity maintains hydrostatic equilibrium at $r = R$. Inasmuch surface temperature as well as surface density are above atmospheric

conditions, interior pressures must be above 1 atmosphere. Low- κ solutions with little excess pressure should represent a low-energy ball lightning with restricted radiative output, as seen by Jennison. Other ball lightning reports specify internal energies in the range 10^6 – 10^8 (ref. 8), and a scorching radiative output of $4.5 \times 10^5 \text{ W}$ (ref. 14). This type should correspond to the high- κ limit of equation (4), where severe density stratification and high surface temperatures imply huge internal pressures. Already for moderate values of κ , the central density and temperature calculated from equation (4) fall in the region of thermonuclear interest. Table 1 gives a possible range of density, temperature and pressure for the case $\kappa R = 9$. Mean density $\bar{\rho} = 1.3 \text{ kg m}^{-3}$ and surface temperature $T_s = 4,000 \text{ K}$ served as reference for the calculation. The surface layer was treated as an ideal gas with atomic weight 14.2, and the central plasma was taken as fully ionised air.

Table 1 Range of parameters derived from hydrostatic equilibrium in an isobaric ball lightning model with $\kappa R = 9$

Parameter	Centre	Surface
Density	$\rho_C = 3.8 \times 10^{-5} \text{ kg m}^{-3}$	$\rho_s = 7.8 \text{ kg m}^{-3}$
Temperature	$T_C = 1.0 \times 10^8 \text{ K}$	$T_s = 4.0 \times 10^3 \text{ K}$
Pressure	$p = 181 \text{ atm}$	$p = 181 \text{ atm}$

The hydrostatic temperature profile of Table 1 is bound to be smoothed by energy transfer from the hot central region to the cooler surface layers. The mode of charge transfer and its effect on the equilibrium conditions in the ball lightning model are charged vortices in a turbulent plasma with: (1) electrical properties of a superconductor; (2) binding energy from density stratification; (3) energy storage in the pressure field.

I thank Professor J. Kistemaker for helpful comments.

Electron-optical observations of ordered FeNi in the Estherville meteorite

S. Mehta, P. M. Novotny, D. B. Williams & J. I. Goldstein

Department of Metallurgy & Materials Engineering, Lehigh University, Bethlehem, Pennsylvania 18015

Scott and Clarke¹, using optical techniques, have recently reported the presence of ordered FeNi (taenite) with the tetragonal $L1_0$ structure (AuCu) in over 40 meteorites. The ordered phase occurs in 10–60 μm diameter regions and in 1–5 μm wide rims of clear taenite containing 48–57% Ni (refs 1, 2). In contrast with disordered γ -Fe-Ni, the ordered taenite is optically anisotropic. The X-ray diffraction pattern and Mössbauer spectrum of ordered FeNi^{3–5} are also similar to that of tetragonal FeNi synthesised using high flux neutron irradiation at 300 °C of a disordered FeNi alloy in the presence of a magnetic field.

Although Mössbauer and X-ray diffraction studies^{6,7} have been used to detect superstructure in bulk samples, these techniques cannot spatially locate the ordered phase within the microstructure. The present study uses various electron-optical techniques, including transmission electron microscopy (TEM), scanning transmission electron microscopy (STEM) and electron probe microanalysis (EPMA) to characterise and to resolve the ordered FeNi phase spatially. In addition, the first TEM evidence (both electron diffraction patterns and centred dark field (CDF) images) for superstructure in clear taenite, is presented.

A thin section of the Estherville meteorite containing a large area of continuous anisotropic taenite ($240 \times 500 \mu\text{m}$) was obtained from the Museum of Natural History, Smithsonian Institution, Washington, DC. The thin section also contains other areas that show optically anisotropic taenite in the form of $5 \mu\text{m}$ wide borders or as small patches that are often associated with schreibersite. Under crossed polars the large taenite field (Fig. 1) shows an intricate network of sub-domains and an irregular granular structure which is characteristic of anisotropic clear taenite^{1,2}. The EPMA trace (Fig. 1 inset) shows an approximately uniform composition across the taenite field. The average Ni content of the taenite is $50 \pm 2\%$ and this value is within the range 48–57% obtained for clear taenite^{1,2}.

Subsequent to the optical and EPMA studies the ($240 \times 500 \mu\text{m}$) clear taenite was extracted from the thin section for TEM and STEM investigations. Adopting a procedure outlined by Nord and James⁸, the clear taenite area was thinned to electron transparency by argon ion bombardment. The electron transparent thin foil was examined in a Philips EM300 electron microscope operating at 100 kV. Using a STEM attachment and X-ray energy dispersive spectrometry (EDS) localised chemical compositions were measured with an X-ray spatial resolution $\leq 50 \text{ nm}$.

TEM examination of the thin foil reveals areas that show characteristically different ion etching behaviour. Several 1–3 μm diameter preferentially thinned regions are observed in a

Fig. 1 Crossed polar reflected light photomicrograph of clear taenite (CT) surrounded by sulphide (S) and kamacite (K) in the Estherville meteorite. Notice the optical anisotropy (indicated by regions of contrast) in clear taenite. Electron probe Ni concentration profile taken across clear taenite is shown in the inset.

Fig. 2 Low magnification transmission electron micrograph of the ion thinned foil of clear taenite shown in Fig. 1. Notice preferentially thinned ordered regions (O) surrounded by disordered, or different ordered variant matrix (D). Lamellar features crossing both regions are magnetic domain walls imaged in slightly defocused conditions.

relatively thick matrix (Fig. 2). As the clear taenite is chemically homogeneous we suggest that the preferential ion etching of certain areas within clear taenite is structural rather than chemical in origin. The parallel black and white lines in Fig. 2 are characteristic of magnetic domain walls imaged in the TEM, and indicate the ferromagnetic nature of both the preferentially thinned and thicker areas.

Electron diffraction from several 20 μm selected areas indicates that the thin foil is a single crystal of taenite. In bright field images various structural defects are observed. These defects have the characteristics of twin boundaries, Neumann bands and a dense dislocation substructure. They are concentrated in the matrix regions and probably formed as a result of shock.

Electron diffraction patterns from all preferentially thinned regions show superlattice reflections in the fundamental FeNi

Fig. 3 Electron diffraction pattern taken from a preferentially thinned region in clear taenite (Fig. 2). The beam direction is $[110]$. The spot marked T is the transmitted spot, those marked S are the superlattice spots. The pattern also shows twin spots marked t which identify the twinning in the matrix as the conventional f.c.c. variety with the twin plane $K_1 = (111)$. Note the absence of superlattice spots in the inset pattern taken from the adjacent matrix.

Fig. 4 Antiphase domain boundary (APB) in the ordered region of clear taenite shown in Fig. 2. Centred dark field image with (001) superlattice reflection. The accelerating voltage is 100 kV. The corresponding electron diffraction pattern is shown in the inset.

(f.c.c.) reciprocal lattice. The superlattice reflections arise from long-range ordering in these regions and indices can be assigned to these reflections on the basis of the LL_0 tetragonal structure. Figure 3 is a symmetric (110) zone axis pattern from an ordered region clearly showing (001) and (110) superlattice reflections. Absence of ordering in the adjacent matrix regions is indicated by disappearance of the superlattice spots in the diffraction pattern (Fig. 3, inset). (The electron diffraction pattern also shows faint twin spots which obey the conventional f.c.c. twinning law with (111) as the twinning plane. Twins were present across both ordered and disordered regions.) As a further confirmation of ordering, CDF images using superlattice spots were used to show the presence of antiphase domain boundaries (APB) within the ordered regions. Figure 4 shows a CDF image obtained with the (001) superlattice reflection. An APB shows up as a dark fringe running across the foil surface in the form of an open loop⁹. We propose, therefore, that clear taenite in the Estherville meteorite contains regions of ordered FeNi phase in a disordered γ matrix. The adjacent areas showing no superlattice spots are either disordered or alternatively (E. R. D. Scott, personal communication) are ordered LL_0 domains in which the {001} ordered planes are in another of the three possible, mutually perpendicular, orientations that could exist and hence are not correctly oriented for diffraction. It was not possible to distinguish between these two explanations since the specimen would have to be tilted to either a (100) or another (011) orientation to observe a different set of superlattice spots. In the natural orientation of this specimen this was not possible. STEM X-ray microanalysis from the ordered and adjacent regions indicates that both have the composition $52 \pm 2\%$ Ni.

Evidence for the presence of coexisting ordered and disordered taenites in other meteorites has also been provided by Mössbauer and X-ray diffraction studies of Albertsen *et al.*⁴. However, their study shows 28% Ni content for the two taenites in which the disordered taenite is paramagnetic. This composition is clearly below that range obtained for clear taenite^{1,2}. More recently, electron microscopy of cloudy taenite in Santa Catharina meteorite by Jago¹¹ revealed two taenites associated with kamacite in a structure which apparently is a precursor to cloudy taenite. Jago¹¹ further reports that one of the taenites became ordered on heating to 400 °C.

We have presented direct TEM evidence for ordering of FeNi in clear taenite. No evidence was obtained for any crystallographic discontinuity between ordered regions and their surrounds. Therefore description of the optical anisotropy in terms of 'ordered grains' (refs 1, 2) is considered inaccurate. There is

also a clear distinction between TEM and Mössbauer results, since in the latter there is no evidence for the presence of both ferromagnetic taenite and ordered FeNi in the same taenite field⁴. This inconsistency must be explored further. The ordered phase may have formed when the parent meteorite body cooled below the ordering temperature of the superstructure ($T_c = 320$ °C) as suggested by Danon *et al.*¹⁰.

We thank E. R. D. Scott and R. S. Clarke Jr for helpful discussions and R. S. Clarke Jr for supplying the Estherville thin section. This work was supported by NASA grant NGR 39-007-043.

Determination of crystal structure of metastable anthracene by a novel method

S. Ramdas, G. M. Parkinson & J. M. Thomas*

A combination of transmission electron microscopy (TEM) and 'atom-atom' computational procedures^{1,2} developed for molecular crystals has led to the discovery and the determination of the crystal structure and lattice dynamics of a metastable, triclinic phase (hereafter designated, II) of anthracene. The new form, which is only 2 kJ mol⁻¹ less stable than the monoclinic, thermodynamically stable parent phase (I), may be generated by the application of compressive force or shear stress approximately perpendicular to the basal plane of I. In essence, the size and shape of the unit cell into which molecules of anthracene are packed is determined from the electron diffraction patterns of the new phase. From the symmetry and space group, determined by TEM, assuming that the individual molecules are as undistorted in II as in I, a 'trial structure' of the 'new' phase may be computed by minimising the total energy as a function of the molecular packing characteristics, knowing the empirically determined³ atom-atom potentials between all pairs of non-bonded atoms. The structure is refined by varying the molecular coordinates, as described below, so as to arrive at a set of lattice vibrations^{4,5} all of which are real in the entire Brillouin zone. The enhanced photo reactivity of phase II compared with I is explicable in terms of the resulting crystal structure.

* To whom correspondence should be addressed.

We recently reported⁶ the facile production of a metastable phase of anthracene which was discovered from analysis of the electron diffraction patterns of anthracene (I) that had suffered stress at room temperature. Phase II is produced topotactically⁷ inside I such that $(001)_{II} \parallel (001)_I$, $(100)_{II} \parallel (101)_I$ and $(010)_{II} \parallel (011)_I$. Moreover, the conversion of I leads to a coexistent bi-phasic matrix of I and II; irradiation of this matrix with UV light rapidly results in the solid state formation of dipara-anthracene (by formation of $C_9-C'_9$ and $C_{10}-C'_{10}$ single bonds at the 'meso' positions of neighbouring molecules).

From the topotactic relationships quoted above, a set of unit-cell dimensions for II may be derived: $a = 8.56$, $b = 6.04$ and $c = 11.22$ Å, $\alpha = 122.6$, $\beta = 101.2$ and $\gamma = 90.0^\circ$ (in terms of the reported crystal structure⁸ of I). But when the standard energy minimisation procedure using appropriate³ 'non-bonded' potentials of the form: $U_{ij} = A/r_{ij}^6 + B \exp(-Cr_{ij})$, was used the resulting structure, although it had a lattice energy only marginally less than that of I, possessed imaginary frequencies for a few lattice vibrations, thereby indicating that this trial structure was untenable. We therefore explored the energetics and dynamics of a range of structures based on slight distortions of this trial structure. We set an upper-limit of $\pm 5\%$ for the degree of mismatch between the cell dimensions of I and II—a figure which is reasonable in view of the absence of observed electron-microscope strain contrast at interfaces of II and I. From the many sets of unit-cell dimensions for II that may be generated on this basis there emerged, after packing analysis (energy minimisation) and lattice dynamical calculations, either: (1) dynamically unstable structure(s); or (2) the stable monoclinic $P2_1/a$ phase (I) or (3) a triclinic structure (space group $P\bar{1}$, $Z = 2$ and cell constants $a = 8.342$, $b = 5.892$, $c = 11.282$ Å, $\alpha = 123.34$, $\beta = 96.70$ and $\gamma = 85.91^\circ$) with no imaginary lattice frequencies (the minimum energy structure quoted in ref. 6 has subsequently been found to be dynamically unstable). Full details of the structure are given elsewhere⁹, but the salient difference is the intermolecular disposition of the two molecules situated at $(1, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, 0)$ as shown in Fig. 1. This new phase II, which does not seem to exist in the bulk phase, readily reverts to phase I in normal conditions of temperature and pressure: at low temperatures its lifetime may be prolonged. As the temporary stabilisation of II could arise from the presence of the topotactic interfaces with I, we have also looked at their energetics and structure using the non-bonded potentials and the energy minimisation procedure.

Using a computational approach in which layers of I and II on either side of an imaginary interfacial plane are in coherent contact (zero mismatch), with lateral mismatches progressively increasing with distance away from the interface, it is possible to estimate the 'excess energy' at the three principal boundary planes that give rise to the topotaxy. Again a pairwise evaluation of non-bonded interactions is undertaken. The 'excess energies' at all three topotactic interfaces are small (roughly a tenth of the surface energy of the respective plane), unlike the typical excess energies at high- and low-angle boundaries in metals (which are, respectively, about a third and a sixth of the corresponding surface energies). Besides the favourable energetics at the interface, we also find that the intermolecular contacts and molecular conformation across the interfaces are analogous to those found within the bulk structures of I or II. These results are in line with our observations in the electron microscope where we have found no direct evidence for mismatch dislocations, strains or clear boundaries between the two phases.

Careful control over the structural and chemical purity of the anthracene crystals and subsequent photo-reaction studies (in the TEM), reveal unmistakably the positive influence of the new phase on dimer formation. Enhanced photoreactivity is exhibited at the compressed regions of the crystal.

Significantly, compared with the situation that prevails for phase I, some of the intermolecular dispositions are different in phase II and at interfaces of I and II. Of particular relevance is the shortening of both the $C_9-C'_9$ and $C_{10}-C'_{10}$ distances between the adjacent molecules $(1, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, 0)$ on proceeding from I

Fig. 1 Illustration of mutual orientation of nearest molecules in phases I (a) and II (b) or crystalline anthracene. Only three molecules in the $(\bar{1}10)$ plane are shown.

to II. The green fluorescence observed in the compressed specimens may also be attributed to the slightly increased overlap between these molecules in II. Also of relevance is the relative ease with which a molecule of anthracene at $(\frac{1}{2}, \frac{1}{2}, 0)$ in phase II may be rotated (with limited hindrance from surrounding molecules) about its long axis, thereby bringing it face-to-face and overlapped with its adjacent molecule at $(1, 0, 0)$. Both these factors will render II more susceptible than I to photodimerisation, in line with observation.

Thus, the present method can be used to elucidate structural information from basic TEM data, starting with a static calculation procedure (lattice-energy minimization) followed by a further refinement using a dynamic treatment (phonon dispersion). Notwithstanding the limits imposed by the approximations inherent in the calculation methods used, it is anticipated that this approach to crystal structure determination should be widely applicable to other organic crystals, especially where problems of small crystal size and the occurrence of polymorphic intergrowths are encountered.

Polar ice evidence that atmospheric CO₂ 20,000yr BP was 50% of present

Robert J. Delmas, Jean-Marc Ascencio
& Michel Legrand

Laboratoire de Glaciologie et de Géophysique de l'Environnement,
BP 53, 38041 Grenoble Cedex, France

Analysis of the air enclosed in polar ice (~0.1 ml per g of ice¹) provides one of the most promising ways of discovering atmospheric composition over the past 100,000 yr. Until now, because of an apparent but not well understood enrichment of CO₂ in the trapped air, all attempts to reconstitute the ancient atmospheric CO₂ content from polar ice have failed²⁻⁶. We have obtained CO₂ contents that can reasonably be considered representative of present or past atmospheric contents using a new method of air extraction. The results reported here, based on the CO₂ analysis of two deep Antarctic cores including the last climatic interchange, strongly suggest that during the coldest part of the last Ice Age (20,000–15,000 yr ago) the atmospheric CO₂ content was half (0.016%) that of today's level (0.033%).

Carbon dioxide extracted in a vacuum from melted ice samples can originate from: (1) air contained in bubbles within the ice; (2) gas which may be trapped or adsorbed by the ice lattice; or (3) the decomposition of dissolved carbonates or carbonate particles which are present naturally or artificially (through contamination) in the solid.

Raynaud and Delmas have previously determined the CO₂ content of ice cores from several polar sites (Greenland and Antarctica) and of various ages (Holocene and Wisconsin periods)⁵. All these determinations showed a large CO₂ enrichment with respect to the present-day composition. The general mean was 0.35% at Camp Century (Greenland) and 0.13% at Byrd Station (Antarctica). We concluded that the gas-solid interaction in the firn is probably responsible for this phenomenon. However, we pointed out that a modification of the initial CO₂ content during storage of the ice core could not be excluded. More recent results⁷ concerning the detailed analysis of an ice core representing ~2 yr precipitation at Camp Century also show a high enrichment of CO₂ (content, 0.1%) in the extracted air.

Results without, and after decontamination of the ice (see text). For each site elevation (m), mean annual temperature (°C) and total gas content in the depth range 100–150 m are given (ml per g of ice) (from ref. 8). Number of determinations are given in parentheses. Decontamination methods: a, water, 20 °C; b, ethanol, -15 °C; c, acid bath, 20 °C; d, ultrasonic acid bath, 20 °C; e, acid bath -12 °C.

Fig. 1 % of CO₂ (v/v) in the air of the bubbles from the Dome C ice core against depth (in metres of ice equivalent). Isotopic values ($\delta^{18}\text{O}$ ‰ continuous line) and dating are as published previously¹⁰. Note the low CO₂ contents between 22,000 and 15,000 yr BP. The present day atmospheric CO₂ content (0.033%) is indicated by a dashed line.

Classical gas extraction procedures and CO₂ content determination have been described previously^{5,8}. The ice core is cut in a cold room with an electrical band saw. All faces of the sample (a cube of 30–50 g) are 'new' to minimise contamination. The sample is placed in a glass vessel which is then mounted in a vacuum line. After melting of ice, CO₂ content is determined in the extracted gas chromatographically. We have investigated first the contribution of carbonates (actually bicarbonates HCO₃⁻) which could be responsible for the CO₂ enrichment. On the basis of a 0.03% CO₂ content in the gas extracted, 1,000 g of ice contains ~30 µl of CO₂ whereas 1 µEquiv. of HCO₃⁻ releases through decomposition 22.4 µl of CO₂. This comparison shows that the total CO₂ measurements are very sensitive to the possible presence of small amounts of carbonates in the lattice. For 32 samples of Dome Summit (66°17'S, 110°32'E) for which the 'classical' gas extraction method gave a mean value of 0.13% of CO₂ ($\sigma = 0.07$), we determined, by a sensitive (± 0.2 µEquiv. l⁻¹) titrimetric method, a surprisingly high mean bicarbonate content of 7 µEquiv. l⁻¹. As estimation of the natural carbonate content leads to much smaller values, contamination of the samples could be responsible for this high carbonation. (The molar ratio HCO₃⁻/Na is 0.005 in sea salt, assumed to be the major impurity (some µEquiv. l⁻¹) in snow at this coastal site.) By rinsing copiously the surface of the solid sample with double permuted water or ethylalcohol we considerably reduced the carbonation.

New determinations of CO₂ in decontaminated polar ice were made as for the carbonate measurements. The results (Table 1) show clearly that the gas extracted from the ice has a CO₂ content which is not significantly different from the present-day air composition. These results contrast strongly with the former reported values. Our experiments explain *a posteriori* the poor reproductibility of the previous CO₂ measurements, the

difficulty of extracting the total CO_2 from meltwater and the high pH values of the meltwater sometimes observed⁷.

To eliminate more completely the contamination problems linked with the ice lattice, we developed a dry extraction method. The solid ice sample (~40 g) was pulverised under vacuum at -40°C in a closed stainless steel container with the aid of two metallic balls for 30 s. About 75% of the trapped gases are released. They were then transferred to the gas chromatograph, as for a wet extraction. We checked that our CO_2 concentration measurements were independent of grinding time, of gas extraction rate, as well as of the state of the sample (contaminated or fractured).

Two deep Antarctic ice cores have been analysed by this method (Dome C and D10). The results (Table 2) are plotted against depth and age in Figs 1 (Dome C) and 2 (D10). The average CO_2 concentration was 0.025% at both locations, that is, much less than published to date and still slightly lower than values obtained using the classical extraction method after decontamination (Table 1) particularly for the deepest fractured

Fig. 2 % of CO_2 (v/v) in the air of the bubbles from the D10 ice core against real depth (in metres). The interpretation of the isotopic profile ($\delta\text{D}\text{‰}$, continuous line) is complicated in this coastal site by glacier flow problems. Climatic fluctuations are given here in terms of variations of $\delta\text{D}\text{‰}$ ($\Delta\delta\text{D}\text{‰}$). They have been reconstituted by Raynaud *et al.*⁹ and apparently include the last climatic interchange. Low CO_2 contents are observed during the coldest period (215–235 m). The present-day atmospheric CO_2 content (0.033%) is indicated by a dashed line.

(and hence possibly contaminated) ice samples. In some cases (113 and 148 m, D10), nearly identical results were obtained (0.033–0.036%) by using either analytical method—a good indication that CO_2 is located essentially in the bubbles. On the other hand, the 'dry' extraction method seems to be the only one convenient for CO_2 analysis of fractured ice cores (even if they have lost important volumes of gases—as is the case for the two cores we studied from a depth below 200 m).

The most interesting feature in Fig. 1 is the marked CO_2 depletion (0.016–0.020%) during the coldest part of the glacial age (15,000–20,000 yr BP). The same is observed at D10, although the dates of the ice layers are still being questioned at this location. The temperature increase (estimated at DC to be $\sim 7^\circ\text{C}$ (ref. 10)) which followed the end of this period is accompanied by a similar trend for CO_2 . However, our results are not accurate enough to conclude whether the increase in atmospheric CO_2 content preceded or proceeded the climatic change. A time lag could exist between the age of the ice and the age of the entrapped gases because the interstitial air of the firn is probably in contact with the free atmosphere for a long time (up to 2,000 yr at Dome C). On the other hand the interstitial air could be also contaminated by older air expelled from deeper firn layers by the slow compaction process. The net result of such effects could be a smoothing of the variations of the initial atmospheric CO_2 content. During the Holocene, the mean values (0.031% at D10, 0.027% at DC) are relatively consistent and essentially in agreement with the estimated pre-industrial values (0.027–0.029%)^{11,12}. The variations of the CO_2 content during this period, particularly at Dome C (six depth levels studies), can be explained by the reported analytical uncertainties (Table 1). Nevertheless, at both locations, the highest CO_2 contents of the Holocene period are obtained around the climatic optimum which immediately follows the climatic interchange¹⁰. The results concerning the oldest samples (ages > 20,000 yr) are difficult to interpret due to dating uncertainties, especially at D10.

Finally although physicochemical processes within the firn (such as adsorption) could also affect the composition of the air trapped in the polar ice^{5,13}, these new results show that the importance of the CO_2 enrichment found in the polar ice gases has been largely overestimated and that the ancient variations of the atmospheric CO_2 content can most probably be reconstructed from deep ice cores.

Berner *et al.*¹⁴ have recently analysed two deep ice cores (Camp Century, Greenland and Byrd, Antarctica) for CO₂ content. Their experimental procedure for extracting CO₂ from the ice was similar to our 'classical gas extraction method'. They consider two different CO₂ fractions (the gaseous CO₂ and the CO₂ in the ice lattice), and their results strongly suggest that the atmospheric CO₂ concentration during the last glaciation could have been a factor of 1.5 lower than today, which is in good agreement with our own results.

We thank Dr W. F. Budd for providing the Dome Summit samples and Dr C. Lorius and D. Raynaud for discussions. This work was supported in part by Ministère de l'Environnement et du Cadre de Vie, the Terres Australes et Antarctiques Françaises, the Expéditions Polaires Françaises and the NSF Division of Polar Programs.

Recent climatic trends and local glacier margin fluctuations in West Greenland

J. E. Gordon

Nature Conservancy Council, Geological Conservation Review Unit, Pearl House, Bartholomew Street, Newbury, Berkshire RG14 5LS, UK

Recent climatic trends in the Arctic have been characterised by a general cooling between the mid-1950s and the late-1960s, followed by a return to warmer conditions in the early 1970s (refs 1, 2). Throughout the Canadian Arctic Archipelago and at Thule in north-west Greenland a marked decrease in summer temperature occurred after 1963, and winter precipitation increased^{3,4}. These changes were accompanied by a lowering of the average July freezing level height by as much as 500 m (ref. 5), decreased glacier mass loss⁴ and increased glaciation³. Here I report similar climatic trends in West Greenland and demonstrate different glacier responses, in particular an advance of cirque and small valley glaciers since about 1968, contrasting with a simultaneous retreat of larger valley and icefield outlet glaciers.

Mean annual and seasonal temperature and precipitation trends for Godthåb (64°10'N, 51°33'W) since 1920 are presented in Figs 1 and 2, based on data provided by the Meteorologisk Institut in Copenhagen. Summer is defined as the months May to September; winter as the months October to April. These groupings approximately encompass the glacier ablation and accumulation seasons, respectively. Spring and autumn are broadly equated with the months May and September, respectively. A major feature of the temperature graphs is the marked cooling in all seasons from about 1966 to 1971 followed by a trend towards warmer conditions after 1971, except in winter. During 1971, 5-yr mean summer temperatures reached their lowest level since the start of continuous records in 1875. Winter and summer precipitation increased sharply in the 1950s and

Fig. 1 Five-year running means of temperature at Godthåb (solid lines) and Sukkertoppen (dotted lines). Data are plotted for the middle year of each five year period. Winter data are plotted for the second year of each winter.

1960s, and the highest 5-yr means since the start of continuous records in 1920 were in 1966 and 1963, respectively. Thereafter, precipitation totals fell, but remained above those for the years 1920 to 1960. Climatic data for Sukkertoppen, 145 km north of Godthåb and the nearest town to the glaciers investigated, are only available from 1960 onwards, but the trends from this date are similar to those for Godthåb (Figs 1 and 2). The origin of the above trends has been related to the development and persistence of a ridge of pressure anomaly over Greenland in the 1950s and 1960s and its sudden collapse after the winter of 1970–71². Manifestations of the climatic deterioration in the form of increased ice-cover of the sea and biological changes have already been reported^{1,2}. I now describe some glaciological effects.

The area at the head of Íkamiut kangerdluarssuat (Fig. 3), 45 km north of Sukkertoppen, is one of spectacular alpine-type glaciation: many cirque and small valley glaciers up to 6 km long

Table 1 Glacier locations, sizes and icefront changes

Glacier	Location		Length (km)	Overall change in glacier front position between 19th century ice maximum extent and 1968–69		Overall change in glacier front position between 1968–69 and 1978

Glaciers 1 to 7 are cirque or valley glaciers; glaciers 8 and 9 icefield outlet glaciers.

are set among mountains rising steeply from sea level to a maximum altitude of 1,755 m, and several outlet glaciers drain an icefield approximately 40 km by 15 km in size at an altitude of about 1,200 m above sea level and existing independently of the Inland Ice. Before about 1968 the glaciers of the Sukkertoppen area had been progressively retreating, although interrupted by several short halts, from the advanced positions of their historical maximum extent in the mid to late nineteenth century⁶. This pattern has been confirmed for seven cirque and valley glaciers and two outlet glaciers investigated during the summer of 1978⁷. The positions of these glaciers in relation to prominent points in their forelands were compared with those on vertical aerial photographs taken in 1968 in some cases and 1969 in others by the Geodætisk Institut, Copenhagen. The two outlet glaciers and the largest valley glacier have continued to recede overall between 1968–69 and 1978 by between 34 and 190 m (Table 1). However, in two of the forelands (6 and 9 in Table 1) the presence of end moraine ridges between the 1968–69 and 1978 ice margin positions indicates temporary reactivation at some stage during this period. In the case of glacier 9 the ridge is 3.5 m high, and the volume of debris clearly represents several years accumulation when compared with that seen melting out from the glacier in 1978. As two recessional ridges superimposed on its proximal slopes are probably push moraines formed during the winters of 1977–78 and 1976–77, I infer that the main ridge was formed between about 1971 and 1975. It is unlikely to have been formed much earlier as it lies inside the 1969 ice margin position. The glacier has since receded by up to 10 m from the main ridge crest. Neither plants nor lichen were observed in the immediate proglacial areas of the three receding glaciers.

In contrast, six of the cirque and valley glaciers have advanced overall from their 1968 or 1969 positions by distances of between 20 and 158 m (Table 1). When visited, they were generally in close contact with fresh moraine and boulder ridges at their margins, and the advance was probably still in progress. In two cases slight recession of 1 to 2 m from the ridges may

Fig. 2 Five-year running means of precipitation at Godthåb (annual, summer and September, solid lines; winter and May, dashed lines) and Sukkertoppen (dotted lines). Data are plotted for the middle year of each 5-yr period. Winter data are plotted for the second year of each winter.

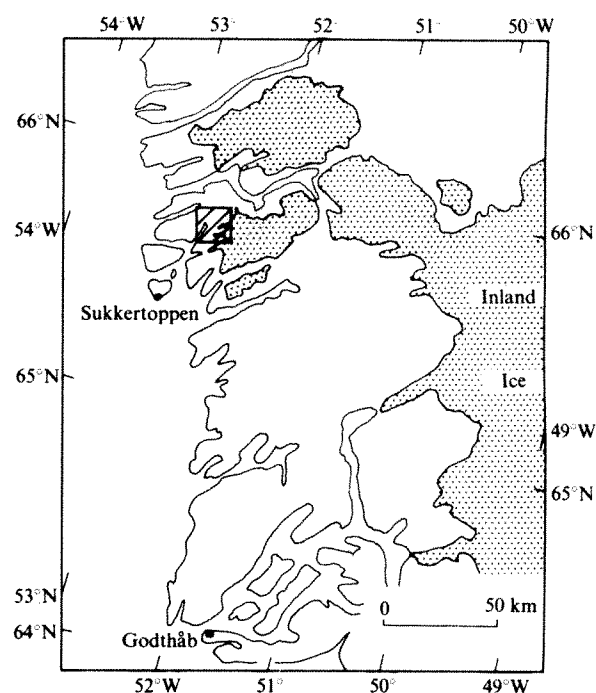

Fig. 3 Location map. The glaciers investigated occur within the shaded square north of Sukkertoppen. Major glaciers only are shown by stippling.

reflect negative summer balances as observations were not made at the start of the ablation season. Plants and patches of moss were often incorporated or disturbed at the distal edges of the marginal debris ridges. Lichen of *Rhizocarpon* species with thalli up to 9 mm in diameter (equivalent to an estimated age of 22 yr) occurred within 15 m of some of the glacier fronts.

The recent frontal changes of the cirque and small valley glaciers are sufficiently similar in direction and timing to argue that they relate to the changing climatic conditions rather than internal instabilities or surges. I therefore comment on possible relationships between the climatic trends and the general response of the glaciers. Theoretically the glaciers will respond relatively rapidly to changes in temperature or radiation conditions because of the immediate effects on ablation in the sensitive snout areas, but there will tend to be a lag in their response to changing precipitation conditions while the effects are propagated down-glacier from the accumulation areas.

The advance of the cirque and small valley glaciers since about 1968 coincides in its first part with a period of decreased summer temperatures and a trend towards colder, wetter springs and colder, drier autumns, and can be seen as a direct response to this climatic deterioration. However, despite a reversal in all these trends after 1971, the glaciers have continued to advance at least until 1978. Therefore, the observed pattern of glacier margin fluctuations matches only in part the recent temperature trends. The continued advance of the glaciers probably reflects a lag in their response to the increased precipitation during the late 1950s and 1960s. The magnitude of this lag is at least 9 yr judging from the fact that precipitation began to decrease sharply after 1969.

The temporary reactivation interrupting the continued recession of one of the outlet glaciers and the largest valley glacier can be explained as a direct response to the climatic cooling, particularly in summer seasons during the late 1960s and early 1970s. However, these glaciers do not seem to have responded significantly to the increased precipitation in the 1950s and 1960s. This could reflect either a lag or a damping of any effects due to the size of the glaciers. The former is more probable because of the magnitude and duration of the precipitation increase. The continued recession of the two outlet

and the largest valley glaciers at present can be explained partly as a direct response to the recent climatic warming and partly as a lag response to the relatively low precipitation during the 1940s and early 1950s. If this is the case, then a minimum lag of 20 to 30 yr in the response of these glaciers to precipitation changes is implied.

The fieldwork was supported by grants to the University of St Andrews Greenland Expedition 1978 from the University of St Andrews, the Carnegie Trust for the Universities of Scotland, the Royal Geographical Society, the Royal Scottish Geographical Society, the Russel Trust, the Gino Watkins Memorial Fund, the Gilchrist Educational Trust and the Drapers' Company. I thank Dr D. E. Sugden for reading the manuscript.

Early Flandrian land and sea-level changes in Lower Strathearn

R. A. Cullingford, C. J. Caseldine & P. E. Gotts

Department of Geography, Amory Building, University of Exeter, Exeter EX4 4RJ, UK

The morphological and stratigraphic studies reported here relate to early Flandrian relative sea-level changes in the carselands, or Postglacial raised estuarine flats, of Lower Strathearn. These data coupled with the study and dating of associated environmental changes by pollen and diatom analysis and radiocarbon assay, have enabled graphs of relative sea-level changes and land uplift to be constructed.

The carselands are backed by the Main Postglacial raised shoreline, whose local altitude is 9.8–10.2 m OD (ref. 1), and whose ^{14}C age has been determined elsewhere in east-central Scotland to be in the range 5,900–7,200 yr BP (refs 2–4). The carse deposits, consisting of estuarine silt and clay, vary in thickness from a thin veneer to well over 10 m, and are extensively underlain by a bed of terrestrial peat, which in turn rests on sandy estuarine deposits. The surface of the latter is shown by more than 250 boreholes sunk by the authors to form a staircase of buried steps separated from each other by distinct bluffs, the foot of each bluff representing a buried raised shoreline.

These morphological and stratigraphic relationships, which are broadly similar to those established in the Forth carselands^{5,6}, suggest the following sequence. A Lateglacial and early Flandrian phase of generally falling relative sea level was punctuated by stillstands and/or transgressive episodes resulting in the formation of what are now buried raised estuarine flats in descending order of age and altitude, the abandonment of the flats being followed by the growth of vegetation, including peat. Later, relative sea level rose again, causing the progressive burial of the peat-covered flats, in ascending order, by the carse deposits, and culminating in the formation of the extensive carseland surface visible today.

The 15 ^{14}C dates from six sites used in constructing the relative sea-level and land uplift curves (Figs 2 and 3) are listed in Table 1, and the locations of the sites are shown in Fig. 1. The data include two ^{14}C dates relating to the culmination of the Main Postglacial transgression at Glencarse⁷ (site 6), in the Carse of Gowrie, as this site is close to, and lies on the same Main Postglacial Shoreline isobase as, the Carey–Cordon area¹.

At Carey (site 1, Fig. 1) a 59 cm-thick bed of highly-compressed peat rests on medium sand, and is overlain by >6 m of carse deposits. The pollen record established by analysis of samples at 1–2 cm intervals throughout the peat and the upper 7 cm and lower 6 cm of underlying and overlying estuarine sediments contains no suggestion of any gaps in the depositional record. Although few unambiguous indicators of a salt-marsh environment are present, a reed-swamp succession may be suggested, especially at the basal transition, by the high frequencies of Gramineae pollen (up to 70% of 500 total land pollen). These are interpreted as reflecting the presence of *Phragmites*, of which there is also macroscopic evidence. The diatom assemblage of the basal 12 cm of carse deposits is dominated by several species of *Fragilaria*, averaging >70% of the total count (1,000 valves). In common with sites 2–5, diatoms are abundant only within and above the peat–carse transition, and the buried estuarine deposits contain only small numbers, which include both marine and brackish-water taxa. The base of the peat (altitude 3.2 m OD) at two different places along the same exposure has been dated at $9,640 \pm 140$ yr BP (I-2796)^{1,9} and $9,524 \pm 67$ yr BP (SRR-72)⁸, giving the approximate date of initiation of peat growth following the withdrawal of estuarine conditions (point 1a, Fig. 2). Pollen evidence confirms this date, with *Betula*, *Juniperus* and *Filipendula* all present in the basal peat samples, as has been found at Main Buried Beach sites in the Forth valley^{10,11}. As the Carey exposure is located close to the buried shoreline (altitude 3.2 m OD) the ^{14}C dates must relate closely to the abandonment of the latter, especially the one derived from the basal 1 cm of peat (I-2796). The Carey buried shoreline is believed to correlate with the Main Buried Shoreline of the Forth valley^{5,6}, which has been similarly dated at about 9,600 yr BP. (J. B. Sissons, personal communication). The top of the peat at Carey (present altitude 3.8 m OD) gave radiocarbon ages of $7,605 \pm 180$ yr BP (NPL-127)^{1,9} and $7,778 \pm 55$ yr BP (SRR-71)⁸, dating the onset of peat burial beneath the carse deposits (1b, Fig. 2). (Note that in ref. 9, the I-2796 date was erroneously recorded in yr BC instead of yr BP.)

At Innernethy (site 2) an 80 cm-thick peat bed rests on the silty sand of an extensive buried estuarine flat. The latter is next below the Carey feature in the staircase of buried flats, and site 2 is located adjacent to the buried shoreline (altitude 2.8 m OD). A 1 cm-thick peat band that occurs within the buried estuarine deposits, 18 cm below the base of the main peat bed, demonstrates that the buried shoreline was formed at the culmination of a transgression. The ^{14}C ages of this thin peat band (2a, Fig. 2; altitude 2.7 m OD) and the base of the main peat bed (2b; altitude 2.8 m OD) date this culmination to between $8,555 \pm 60$

Fig. 1 Location of sites: 1, Carey; 2, Innernethy; 3, Cordon; 4, Culfargie; 5, Kintillo; 6, Glencarse. The heavy, continuous line represents the Main Postglacial Shoreline, marking the inner edge of the carselands. Land above 15 m OD is stippled.

(SRR-1399) and $8,505 \pm 50$ yr BP (SRR-1398). These dates are statistically indistinguishable at the 95% level from the only published date of $8,690 \pm 140$ yr BP (I-1839)^{4,6,10} relating to the Low Buried Beach in the Forth valley, with which the Innerneath buried flat should correlate by morphological analogy. This may imply that the Low Buried Shoreline was abandoned about 8,500 or 8,600 ^{14}C yr ago, rather than the 8,800 yr usually quoted^{6,13}, a possibility that is reinforced by the basal peat date at site 3. Apart from a brief appearance of *Chenopodiaceae* corresponding to the thin peat band within the buried estuarine deposits, the only apparent vegetational succession is at the peat-carse boundary, where a sequence of freshwater environments may be indicated before the onset of carse deposition (2c; present altitude 3.6 m OD) at about $7,530 \pm 50$ yr BP (SRR-1397). The diatom record in the carse deposits suggests marine and brackish water conditions, as indicated by *Paralia sulcata* (Ehrenberg) Cleve, *Rhaphoneis surirella* (Ehrenberg) Grunow ex Van Heurck and *R. amphiceros* (Ehrenberg) Ehrenberg¹².

At Cordon (site 3) a riverbank exposure at the front of the same buried flat on which site 2 is located shows a similar stratigraphy to that at site 1 (ref. 1). At both transitions the appearance of *Compositae*, *Chenopodiaceae*, *Plantago* sp., *Filipendula*, *Rosaceae*, *Typha angustifolia* and *Lemnaceae* may indicate a succession of salt-marsh and freshwater communities as suggested in the Forth valley¹¹. Marine and brackish water diatoms are prevalent within the basal carse assemblage with *Paralia sulcata* and *Rhaphoneis surirella* averaging over 50%. The basal peat date (3a, Fig. 2; altitude 2.8 m OD) is $8,370 \pm 45$ yr BP (SRR-1147), suggesting the removal of estuarine conditions slightly later than at site 2. This indicates abandonment of the frontal edge of the estuarine flat at a measurably later date than that of the shoreline 1 km to landward. The reappearance of estuarine conditions and initiation of peat burial (3b, Fig. 2; present altitude 3.2 m OD) occurred about $7,525 \pm 50$ yr BP (SRR-1394).

The basal peat dates at sites 1–3 all relate closely to the abandonment of two now-buried estuarine flats, the older and higher of which is the Carey flat. Three distinct buried steps occur above the Carey feature, and the rather thin peat on two of them has been dated at sites 4 and 5 (Fig. 1, Table 1). These higher buried steps are necessarily older than the lower ones already considered, yet the basal peat dates are much younger than at sites 1–3, and in fact differ little from the ages of the topmost peat layer at the latter sites. This suggests a lengthy

Fig. 2 Early Flandrian relative sea-level changes in the Carey-Cordon area, Lower Strathern. Horizontal bars extend one standard deviation either side of the ^{14}C dates.

hiatus between abandonment of the flats and the start of peat growth, and that the latter was a response to the rising groundwater level associated with the Main Postglacial transgression. The basal peat dates (4a and 5a, Fig. 2), although associated with marine transgression, cannot therefore be related to specific relative sea levels, and the higher buried flats remain undated.

Thin compacted peat at Culfargie (site 4) and Kintillo (site 5), 19 cm and 8 cm thick respectively, rests on fine sand and is overlain by 1.6 m and 3.5 m respectively of carse silty clay. Increased evidence of aquatic taxa is evident in the carse deposits at both sites and at Kintillo a sequence of freshwater and salt-marsh communities is suggested similar to that found at Cordon. Marine influence in the carse is also indicated by the abundance of *Paralia sulcata*. The basal peat dates at Culfargie

Table 1 Summary of details of radiocarbon-dated sites in Lower Strathern

* Riverbank exposure.

† Temporary excavation.

‡ These dates are not plotted in Fig. 2 because they were obtained on rather thick (4-cm) samples, and therefore relate less closely to the lithostratigraphic boundaries than the other dates, which were obtained from 1-cm thick samples.

(4a, Fig. 2; present altitude 4.6 m OD) and Kintillo (5a, present altitude 6.6 m OD), of $7,780 \pm 50$ yr BP (SRR-1396) and $7,465 \pm 55$ yr BP (SRR-1401) respectively, are verified by the high values for *Corylus/Myrica* pollen. Transgression of the peat surface occurred around $7,555 \pm 50$ yr BP (SRR-1395) at Culfargie (4b, Fig. 2; present altitude 4.8 m OD) and $7,180 \pm 55$ yr BP (SRR-1400) at Kintillo (5b, Fig. 2; present altitude 6.7 m OD).

In using peat-top dates to construct a relative sea-level curve account must be taken of the peat compaction that accompanied and followed burial by the carse deposits (compaction of the sandy sub-peat materials is assumed to have been negligible). Peat compaction at sites 1, 2 and 4 was estimated by comparing the mean dry bulk density value for an uncompacted monocotyledonous peat at Hole of Clie (NO 2034 2291), in the Carse of Gowrie, with similarly derived values for the buried peats in Lower Strathearn, on the assumption that the fossil peats, before burial, had a comparable bulk density to the surface peat, and that the amount of subsequent compaction is directly proportional to the increase in bulk density. To allow for variations in bulk density within the peat, the mean value for each site was derived from measurements carried out at vertical intervals of 1–4 cm through the peat. The estimated values for compaction at sites 1, 2 and 4 range from 40 to 68%, and in the absence of direct measurements at sites 3 and 5, an overall mean value of 52% was used at those sites. The estimated original altitudes of the peat surfaces at the time they were transgressed by the sea are shown in Fig. 2.

The age and altitude of the Main Postglacial Shoreline, marking the culmination of a major transgression, have been measured at Glencarse (site 6), where a 30 cm-thick layer of carse deposits is underlain and overlain by peat. The buried peat was transgressed (6a, Fig. 2) about $6,679 \pm 40$ yr BP (SRR-1150), and peat growth on the abandoned surface of the carse deposits (6b; altitude 9.8 m OD) was under way at $6,083 \pm 40$ yr BP (SRR-1151)⁷.

Two characteristics of the relative sea-level curve (Fig. 2) as yet unexplained are the transgressive nature depicted for the Carey buried shoreline (point 1a) and the fall of relative sea level between points 3a and 3b. The former is in line with the transgressive nature suggested for the correlative Main Buried Shoreline in the Forth area^{6,14}. The latter is suggested by a buried channel excavated to a few metres below OD near the present River Earn^{1,15}. This low point on the curve occurs between $8,370 \pm 45$ and $7,525 \pm 50$ yr BP, whereas the equivalent trough in the Forth curve is dated to between $8,690 \pm 140$ and $8,270 \pm 160$ yr BP (ref. 4). However, the discrepancy may be negligible when account is taken of the wider timespan delimited for this event by the available Lower Strathearn dates, and the possibility that the low relative sea level occupied a very brief timespan after $8,370 \pm 45$ yr BP.

The relative sea-level curve (Fig. 2) is primarily the net result of isostatic land uplift and eustatic sea level changes. A curve of land uplift (Fig. 3) for the period 9,500–6,500 yr BP was constructed by a similar method to that of Sissons and Brooks⁴.

Fig. 3 Land uplift in the Carey-Cordon area between 9,500 and 6,500 yr BP. The graph shows total land uplift between each date and the present.

Land uplift at 500-yr intervals was calculated by adding the amount by which world sea level was below the present level at each date, according to a particular published eustatic curve, to the contemporary relative sea level in Lower Strathearn as shown in Fig. 2, and subtracting 2 m to compensate for the fact that the data in Fig. 2 relate to former estuarine shorelines and therefore to high water mark. Curves were drawn for all eight eustatic curves^{16–23} not rejected as unsuitable according to the criteria used by Sissons and Brooks, and the results averaged to produce Fig. 3. The form of the curve is strikingly similar to the Forth uplift curve, the magnitude of uplift being less in Lower Strathearn because of the greater distance from the centre of uplift.

We thank the NERC for the award of a Research Studentship to P.G.; the NERC, the Scottish Universities Research and Reactor Centre, and particularly Dr D. Harkness, for radiocarbon dates; Dr E. Y. Haworth for assistance with diatom techniques; and the University of Exeter for help towards fieldwork costs.

Acidification of lakes and streams is a serious water quality problem in high elevation granitic ecosystems in the northeastern US^{1–3}. An important consequence of acidification is the mobilisation of aluminium from the edaphic to the aquatic environment^{3–5}. Elevated levels of aluminium may have serious ramifications for biological communities, particularly fish, inhabiting acidified aquatic systems^{5,6}. In this study, water quality data were collected from several acidified lakes and streams in the Adirondack region of New York state. The purpose of this investigation was to characterise aluminium chemistry in these acidified waters and to assess the relative toxicity of soluble aluminium species to fish. Aqueous aluminium speciation was found to be highly variable in Adirondack waters, and its effect on fish was also variable.

Fig. 1 Temporal changes in pH, total organic carbon (TOC) and aluminium forms for Canachagala Creek from August 1977 to August 1978. Low pH and high levels of labile monomeric (inorganic) aluminium were observed after rainfall (15 August, 27 September) and during snowmelt (15 March, 2 April and 23 April). Low water flow conditions produced elevated pH values and decreased labile monomeric (inorganic) aluminium levels. TOC and non-labile (organic) aluminium were generally high in the autumn and summer and low in the winter and spring. ○, Total aluminium; □, total monomeric aluminium; △, non-labile (organic) monomeric aluminium.

Three lakes in the southwestern part of the Adirondack Mountain Region were investigated—North Lake (74°55' W, 43°43' N; elevation 545 m); Big Moose Lake (74°50' W, 43°30' N; elevation 556 m); and Little Moose Lake (74°55' W, 43°42' N; elevation 545 m) and their tributaries were sampled over the course of a year. The edaphic, climatic and physiographical features of the Adirondack Region have been described by Schofield¹.

Three separate aluminium measurements were made on water samples using a colorimetric (ferron) method⁷. Measurements included total aluminium (samples acid digested before analysis), total monomeric aluminium (samples analysed without acid digestion) and non-labile monomeric aluminium (aluminium separated by a cation exchange chromatography technique and analysed as monomeric aluminium). From these measurements, the total aluminium content of each sample could be subdivided into three fractions. Non-labile (organic) monomeric aluminium was measured directly and included organically chelated aluminium. The second fraction, labile (inorganic) monomeric aluminium, was determined as the difference between total monomeric aluminium and non-labile (organic) monomeric aluminium. This fraction includes free

aluminium and aqueous inorganic complexes (fluoride, hydroxide and sulphate). The third fraction, acid soluble aluminium, was determined as total aluminium minus total monomeric aluminium and includes aluminium forms that require acid digestion before analysis (polymeric, colloidal, extremely stable organic and hydroxy organic complexes). pH was measured potentiometrically; fluoride was measured potentiometrically with a fluoride-selective ion electrode; sulphate was measured with the turbidimetric method and total organic carbon was measured by sample oxidation and IR detection of carbon dioxide using an organic carbon analyser. The labile inorganic fraction of monomeric aluminium was subfractionated using thermodynamic calculations into free (aquo) aluminium and fluoride, sulphate and hydroxide complexes of aluminium. Details of the analytical procedures and thermodynamic calculations used here are given by Driscoll⁸.

Some typical temporal changes in measured aluminium, pH and total organic carbon for Canachagala Creek, a tributary of North Lake, are given in Fig. 1. The relatively high concentrations of aluminium are representative of those found at the other sampling sites.

Table 1 Estimated 50% survival times of brook trout (*Salvelinus fontinalis*, Mitchill) in synthetic soft water solutions containing aluminium and aluminium complexing ligands

pH	Ligands added	Total aluminium concentration mg l ⁻¹	% Survival after 14 days		Estimated 50% survival time (h)	
			Mean	Range	Mean	Confidence limits
5.2	—	0.02	99	95–100	>500	—
	—	0.42	28	20–30	115	88–150
	Fluoride	0.50	45	35–45	202	136–302
4.4	Citrate	~0.5	96	87–100	>500	—
	—	0.01	95	80–100	>500	—
	—	0.48	42	27–53	256	213–306
4.4	Fluoride	0.47	71	67–80	472	354–629
	Citrate	~0.5	82	40–100	>500	—

50% survival times are maximum likelihood estimates based on a logistic model. Experiments were run for 14 days (336 h). Estimated survival times greater than the length of the experiment are based on extensions of the non-linear regression and are subject to large uncertainties. Thermodynamic calculations indicate that levels of ligands added should chelate nearly all aluminium present. Fluoride was added as NaF at 0.5 mg l⁻¹ F; citrate at Na₃H₅O₄ at 11.7 mg l⁻¹ C, at pH 4.4. At pH 4.4, all solutions were adjusted for equivalent Na levels (9.1 mg per l Na). The presence of citrate interferes with the measurement of aluminium. Aluminium levels are based on subsamples of water within experimental units. Each treatment had four replicates with 15–20 fish per replicate.

Periods of low pH were observed in the late summer and autumn after rainfall and during spring snowmelt. During the summer (1978) conditions were dry and pH levels consequently increased. During low pH conditions, total aluminium levels increased dramatically. However, the two fractions of monomeric aluminium (inorganic and organic) responded differently to changes in hydrogen ion activity. Increased levels of labile (inorganic) aluminium (Al³⁺ and aluminium fluoride, hydroxide and sulphate complexes) accounted for most of the response to decreasing stream pH and increasing flow. During high pH conditions, the inorganic fraction of aluminium was substantially reduced.

Variations in organically chelated aluminium seem to be independent of pH but are significantly correlated with total organic carbon measurements ($P < 0.0001$). In the tributaries studied, total organic carbon and non-labile (organically chelated) aluminium levels were low in the winter and spring and high in the summer and autumn. Therefore, the large fluctua-

tions in total aluminium concentration with pH in streams may be largely attributed to large fluctuations in the labile (inorganic) fraction of aluminium.

Aluminium forms strong complexes with hydroxide, fluoride, sulphate and dissolved organic ligands⁹⁻¹¹. All these potential aluminium ligands are present in the dilute acidified waters of the study lakes and streams. Results indicate that non-labile (organic) aluminium is generally the predominant fraction of aluminium in these waters. Thermodynamic computations indicate that fluoride complexes are generally the dominant inorganic aluminium species. Free (aquo) aluminium and aluminium hydroxide complexes were predicted to be present in lesser amounts and aluminium sulphate complexes were generally insignificant.

Elevated levels of aluminium in acidified surface waters may have serious effects on fish and other aquatic biota. Schofield and Trojnar⁶ indicated that levels of aluminium may be a primary factor limiting survival of trout stocked into acidified Adirondack lakes. However, speciation of aluminium was not considered in their study or in other studies of aluminum toxicity^{5,12}. It is generally accepted that complexation alters both distribution and toxicity of trace metals^{13,14}. Laboratory experiments from this study suggest that such conclusions are also applicable for aluminium.

Brook trout fry (*Salvelinus fontinalis*, Mitchell) were exposed in soft water to aluminium as the free ion and complexed with hydroxide, fluoride and/or citrate (Table 1). Fry were held in 8-l polyethylene units (20 fry at pH 5.2, 15 fry at pH 4.4 per unit, mean length 22–23 mm) with stock solutions changing at a rate of ~8 l per day. Stock solutions were prepared at least one day before use. Experimental units were aerated and temperatures ranged from 9 to 17 °C. Soft water was prepared with a Culligan reverse osmosis system using Ithaca city tap water and dechlorinated with a Barnstead organic removal filter. Basic cation concentrations in the softened water were 2–4 mg l⁻¹ Ca, 0.4–0.7 mg l⁻¹ Mg, 1.2–1.5 mg l⁻¹ Na and 0.2–0.4 mg l⁻¹ K. Total fluoride levels were less than 0.01 mg l⁻¹ F; sulphate levels were less than 5 mg l⁻¹ SO₄. Solutions were acidified with hydrochloric acid.

Treatments with excess fluoride or citrate decreased the toxicity of aluminium solutions (Table 1). Survival of brook trout fry after 14 days in treatment waters with 0.5 mg l⁻¹ Al and 11.7 mg l⁻¹ C citrate was 87% or greater at pH 5.2 and 40% or greater at pH 4.4, and not significantly different from control solutions at equivalent pH values. Additions of fluoride to acidified aluminium solutions also increased survival ($P < 0.001$ at pH 5.2, $P < 0.10$ at pH 4.4, Table 1). However, the mitigating effect of fluoride complexation on aluminium toxicity was less than that of organic complexation. Inorganic aluminium forms, therefore, seem to be the major species of concern with regard to aluminium toxicity in fish. As a result of reactions with hydroxide, aluminium toxicity to fish is pH-dependent. Schofield and Trojnar⁶ report increasing brook trout mortality and gill damage with increasing pH over the range 4.4–5.2 at fixed total aluminium levels (0.2–0.5 mg l⁻¹ Al).

Evaluation of aluminium speciation in acidified Adirondack waters indicates that organically complexed (non-labile monomeric) aluminium is the dominant form (Fig. 1). As complexation of aluminium with organic ligands seems to eliminate its toxicity, measurement of total aluminium concentrations may lead to a substantial overestimate of the potential aluminium-induced toxicity of acidified Adirondack waters. A comparison of mortalities of white sucker fry (*Catostomus commersoni*, Lacepede) in natural waters and in synthetic acidified water solutions containing aluminium (without additional complexing agents) supports this conclusion (Fig. 2).

For experiments with white sucker fry, 5-l polyethylene containers with 20 fry per unit were used. Approximately 1.5 l of stock solution was added to each experimental unit four times per day. Units were aerated and temperatures ranged from 17 to 19 °C. Two separate experiments were carried out at pH 5.0: 15–20 July 1978, mean length of fry at start of experiment

14.0 mm; and 7–12 August 1978, mean length of fry 18.7 mm. The sensitivity of white sucker fry to acidity and aluminium changes rapidly with age during the first few weeks after hatching (J. P. Baker, unpublished data). The fry become markedly less sensitive to low pH levels with time, but there may be a small increase in sensitivity to aluminium with increasing age.

Mortality rates of white sucker fry in three naturally acidified Adirondack waters (pH 5.0) appear to be determined by the levels of labile inorganic aluminium present (Fig. 2).

Water quality in dilute Adirondack waters is extremely variable, particularly with regard to organic carbon and hydrogen ion concentration. These variations have considerable effect on the aqueous aluminium chemistry, which in turn affects the survival of fish populations. Surges of labile (inorganic) aluminium into Adirondack streams during snowmelt and heavy rainfall are potentially lethal to eggs and fry. In addition, the ameliorating effect of organic complexation on aluminium toxicity suggests that lakes and streams with high organic carbon content may be suitable for successful fish production despite

Fig. 2 Estimated 50% survival times (with 95% confidence intervals) of white sucker fry (*Catostomus commersoni*, Lacepede) at pH 5.0 in synthetic soft water solutions containing aluminium and in natural lake (Big Moose Lake, North Lake) and stream (West Pond Outlet, a tributary to Big Moose Lake) waters. 50% survival times are estimated as described in Table 1. Each value represents three or four replicate experiments with 18.7 mm fry with no aluminium added, survival was 95–100% after 5 days, and no 50% survival time was estimated. Mean fry length: a, 14.0 mm; b, 18.7 mm.

moderately low pH and high total aluminium levels. A detailed understanding of aluminium chemistry is essential to enable the effect of aluminium on the development of indigenous fish to be evaluated.

Motion smear

David Burr*

Craik Laboratory, Department of Experimental Psychology, Cambridge CB2 3EG, UK

It is well known that the visual system summates signals over time, about 120 ms in daylight^{1,2}. Although this summation has the obvious advantage of enhancing visual sensitivity, it creates the potential problem of motion smear when viewing moving targets, whose images are also summated over time³. Here I report some measurements which reveal that provided the moving target is exposed for long enough to elicit a clear sensation of motion, the amount of smear is far less than may be expected. This suggests that the visual mechanisms which signal motion are also responsible for signalling a clear unsmear perception of the target in motion.

In addition to the threshold measurements of temporal summation it is also well established that super-threshold stimulation leads to a sensation which persists in vision for some time after the termination of the stimulus⁴, again, for about 120 ms in daylight^{5,6}. Perhaps the most direct measurements of the duration of this persistence were made by Ross and Hogben⁷ with dynamic random dot patterns, continuous sequences of brief flashes of light displayed at random positions on an oscilloscope face. Although only one dot is physically imaged on the

retina at any one time, an observer sees not just one, but a whole screen full of dots, in fact, all those that were displayed during the previous 120 ms. Clearly, under these circumstances, the neural sensations greatly outlast the duration of the visual stimulus.

This fact is of little consequence when viewing a stationary scene, but for moving targets, it poses the problem of motion smear. Objects travelling at even moderate speed cover a perceptible distance in 120 ms. If the same rules of visible persistence apply for moving scenes as for random dot patterns, we may expect moving objects to seem smeared and elongated in the direction of motion. This is illustrated by the photograph of Fig. 1, which was taken with a 125-ms shutter speed. Although the buildings all have good definition and contrast, the images of the people walking in the foreground are smeared beyond recognition. However, in natural viewing conditions, the images of moving objects always appear sharp and clearly defined, certainly very different from Fig. 1. Only very rapid image motion creates perceptible smear. Admittedly, with free viewing, the eyes will pursue a target of interest, but this does not solve the general problem, as it in turn introduces retinal motion of the background. What, then, are the mechanisms of vision that prevent motion smear?

Although this problem is fundamental to the understanding of dynamic visual perception, it has received surprisingly little attention. Many measurements have been made on the effect of image motion on acuity^{8,9}, but these do not necessarily reflect the more subjective perceptual qualities of smear or apparent elongation. Two investigations which do bear on this question report that the clarity and veridical perception of a target in

Fig 1 Vision through a 125-ms temporal window. Although much evidence suggest that the visual system integrates light for 125 ms, our every day perceptions differ markedly from a photograph taken with this integration period (shutter speed).

Fig. 2 The apparent length of the motion streak of dots moving along a constant linear trajectory, as a function of exposure duration. For durations of up to ~30 ms, the apparent length increases with increasing duration, as may be expected were light to be integrated over this period. However, at durations of longer than 30 ms, the apparent length decreases with increasing durations—the further the dots travel, the shorter they appear. The error bars each represent 2 standard errors, averaged over all conditions.

motion are enhanced by the prior and post exposure in locations at either end of the motion sequence^{10,11}. Here I show that even without pre- and post-viewing of stationary targets (which, given the filtering properties of vision, alters the effective visual velocity¹²), the amount of apparent elongation or smear is far less than might be expected on the basis of visual persistence⁷.

With a simple matching technique, I have measured motion smear as a function of the duration of exposure to the motion sequence. The measurements were made by matching the length of a short stationary line to the apparent length of dots in an array of motion, using a multiple interleaved staircase procedure under computer supervision¹³. The observer saw a short sequence of moving dots, immediately followed by a continuously visible stationary line. By pressing the appropriate button, he indicated which of the two stimuli seemed to be longer. Depending on his response, the length of the line was either incremented or decremented on the next trial of that condition. The apparent length, taken as the mean of the previous 15 trials, was measured separately three times to give a rough estimate of measurement error. The stimulus pattern was an array of 100 dots in random locations, intensified on an oscilloscope face (p15 phosphor) to a contrast 100 times their visibility threshold against a uniform background luminance of 30 cd m⁻². The dots were caused to move by displacing them successively at 5-ms intervals between each brief (4 μ s) intensification, on some trials to the left and on some to the right, the two directions being presented in random order. Short presentations of unpredictable direction of motion precluded the possibility of pursuit eye movements¹⁴. The screen was vignettted down to a 5° diameter circle by a mask of the same mean luminance placed outside the observer's field of focus, so that the dots faded smoothly out of view. Measurements are reported for two observers, D.B. and M.L., but the effect has been verified qualitatively with many observers, and indeed, can be readily verified by anyone with access to basic visual display facilities.

The results are shown in Fig. 2. Dots exposed for long durations, which travel over a larger retinal region, may be expected to seem more elongated than those exposed only briefly. Indeed, if all the light impinging on the retina were seen simultaneously, as with the dynamic random dot patterns, the perceived length of the streak should be equal to the distance covered by the moving dot. However, this is far from being the case. At short durations (up to 20–30 ms) the amount of motion smear does increase with duration, but at longer durations, the perceived length actually decreases with duration—the further the dots travel, the shorter they seem. Whereas with brief presentation times one sees an array of almost stationary line segments, at longer durations the stimuli are unquestionably small dots in motion, with no hint of elongation along their

trajectory, except when moving at the fastest speed, 15 deg s⁻¹. However, even at this speed the apparent length was only 2 or 4 arc min (for D.B. and M.L.), compared with the 100 arc min the spot traverses during the 120 ms of 'visual persistence'.

Not only was there less elongation of the dots, but also the sensation of motion became much stronger at longer durations. All the stimuli seemed to move to some extent, but with brief exposure times the sensation was quite weak. The non-occurrence of motion smear seems to be linked to the perception of smooth motion. Only when the motion seemed smooth and realistic was the target seen as a small, sharp, unsmearred dot. This suggests, that, contrary to the currently favoured idea of separate analysis of pattern and motion^{15,16}, the mechanisms of vision specialised to detect motion are also responsible for the analysis of the spatial form of the target in motion. Brief glimpses of a motion sequence fail to activate these mechanisms, activating instead mechanisms which, like a camera of long exposure, signal motion smear. A more detailed account, explaining these and other similar results in terms of the known spatial and temporal tuning properties of visual mechanisms, is in preparation.

I thank Dr Fergus Campbell for the use of his laboratory facilities and Professor Horace Barlow for helpful comments on the manuscript. A Hackett Studentship from the University of Western Australia supported me during this research.

Mastectomy and mammary glands in reproductive control in the goat

M. Peaker & F. M. Maule Walker

ARC Institute of Animal Physiology, Babraham, Cambridge and The Hannah Research Institute, Ayr KA6 5AL, UK

Little attention has been paid to the role of the mammary glands in reproduction apart from the suppression of reproductive activity during lactation in some species. A hint of greater involvement, however, stems from two observations in the goat. First, Linzell¹ reported that while developing his technique of transplanting mammary glands to other sites in the body in order to gain access to the mammary artery, the incidence of reproductive disturbances (infertility, abortion and apparently inexplicable maternal death at parturition) seemed greater in goats which had lost mammary tissue post-operatively, or which retained only one mammary gland, than in others in the herd and second, the mammary glands may significantly influence the concentration of a hormone in the general circulation²⁻⁵. Moreover, in some marsupials there is evidence that the mammary glands are involved in the control of reproduction, for example, denervation of the mammary glands during lactation initiates development of the diapausing embryo⁶. In view of the importance of reproductive integration in the artificial control of fertility, we have followed up these clues by investigating the effects of mastectomy in the goat, a species with a seasonal, rather than a lactational, anoestrus. We report here that the oestrous cycle was markedly disturbed by mastectomy and that fertility, and possibly also the length of gestation, seemed to be affected.

Table 1 Effects of mastectomy on oestrous cycles of goats approximately 1 yr after operation (s.e.).

	Length of oestrous cycle* (days)				Duration of behavioural oestrus (h)	
	1st	2nd	3rd	4th	1st	Subsequent
Intact controls (5)	22.0 ± 1.48	21.6 ± 0.25	21.4 ± 0.25		approx. 30	approx. 30
Operated controls (5)	24.4 ± 0.51	21.0 ± 0.01	21.6 ± 0.25		approx. 30	approx. 30
Mastectomised (5‡)	8.4 ± 0.40	13.0 ± 2.45	17.0 ± 1.41	14.3 ± 2.21	115 ± 13.9	approx. 30
	$P < 0.001$	$P < 0.01$	$P < 0.05§$			

Values given are means ± s.e. P values are with respect to both intact and operated groups except that marked §, $P < 0.01$ compared with the operated controls.

* First day behavioural oestrus observed = day 1 of cycle.

† Between first and second oestrus, and so on.

‡ One goat developed hepatitis during second cycle and had to be killed.

Both mammary glands were removed, under halothane anaesthesia, from five goats aged 9 months. The operations were done in early December (that is during the breeding season) 3–7 days after the last observed oestrus. No sham operation could be devised to mimic closely the full procedure of mastectomy. Therefore, the operated animals were compared with two control groups—five intact goats and five which had been subjected to udder surgery (such as ligation of blood vessels crossing between the two glands⁷) akin to that completed by mastectomy but in which neither the main nerves nor major blood vessels had been divided. Although in young virgin goats mastectomy is a relatively minor surgical procedure, the results obtained in the first breeding season are not presented to avoid the possibility that the effects observed might be attributed to nonspecific effects of surgery. However, it is interesting that one goat never returned to oestrus for mating and in two others fertility seemed to be reduced.

In the second breeding season, approximately 1 yr after operation, the goats were observed several times each day for the signs of behavioural oestrus (bleating, restlessness and tail-wagging). The mastectomised goats showed the first signs of behavioural oestrus during a period in the autumn indistinguishable from that of other goats in the herd; in other words they emerged from seasonal anoestrus at the same time. However, major differences then became apparent. Thus the first oestrus of the season lasted 3–6 days in the mastectomised goats compared with approximately 30 h in the controls. Moreover, the first cycle (between the onset of the first and the second oestrus) was significantly shorter in the mastectomised animals (mean 8.4 days) than in either the intact (22 days) or operated (24.4 days) controls. Subsequent cycles were also significantly shorter, although the duration of behavioural oestrus was not apparently affected (Table 1). The mastectomised goats were all mated at the second oestrus but all returned to oestrus at least twice more (two, two, three and four times, respectively, in the four surviving goats (Table 1), even though they were mated each time. By contrast, the controls that were mated first (with the same males) at the fourth oestrus showed no further cycles. Moreover, in the rest of the herd mated at the first to fourth oestrus of the season, only four out of 80 matings (in two seasons) did not result in conception at the first attempt.

The gestation period (in days) of the four goats that became pregnant in their first season (number of young delivered in parentheses) were: 146 (2), 146 (1), 146 (1) and 147 (1), and in the second season: 143 (2), 147 (1), 147 (2) and 148 (2). Because the number of young carried seems to affect gestation period, comparison with controls is difficult. Nevertheless, for those bearing one kid the gestation periods were all shorter (by a median of 4.5 days) than the median of 151 days for goats in the herd⁸; similarly, for those bearing two the gestation periods were all shorter (by a median of 3.5 days) than the median of 150 days⁸. All young were delivered alive.

These results indicate that mastectomy had a pronounced effect on oestrous cycles in the goat; in addition, fertility, and possibly also the duration of pregnancy, seemed to be affected. Further experiments are in progress, but it would seem that

there is an alteration in the 'fine-tuning' of reproductive processes. It can be argued that it is the presence of mammary tissue rather than lactation which is of major importance in the effects described because there seems to be no difference between lactating and non-lactating intact goats in terms of the periodicity of oestrous cycles or of fertility (our unpublished observations).

Although Linzell¹ found no apparent effects of mastectomy on reproduction in the guinea pig, the strategies of reproductive control used by mammals are so diverse that it remains to be seen whether reproductive difficulties supervene in individuals of other species which suffer loss of mammary glands or tissue, either surgically as in women with mammary tumours, or following infection as in mastitis in farm animals.

Evidence for selection following perturbation of allozyme frequencies in a natural population of *Drosophila*

J. S. F. Barker* & P. D. East

Department of Animal Husbandry, University of Sydney, NSW 2006, Australia

There is now ample evidence for the ubiquity of genetic variation at allozyme loci in many species^{1,2}, but the extent to which this variation is actively maintained by natural selection remains unresolved. Although various approaches have suggested the importance of selection at some allozyme loci in laboratory populations^{3–6}, to be fully convincing, evidence for natural selection must finally come from studies on natural populations. Inevitably, this will entail an understanding of and the potential to manipulate both the ecology and genetics of the population. Because sufficient is known of the ecology, breeding site, nutritional requirements and field behaviour of at least some species of the cactophilic *Drosophila*, we^{7–9} and others¹⁰ have chosen them for experimental evaluation of the forces operating to maintain genetic variation. If genetic variation at some locus is being actively maintained by natural selection, the action of this selection should be detectable following artificial change in gene frequencies produced either by adding certain genotypes to the population, or by removing them from it. Jones and Parkin¹¹ have reported unsuccessful attempts to detect selection by such

* Present address: Department of Animal Science, University of New England, Armidale, NSW 2351, Australia.

perturbation experiments in *Cepaea* and *Drosophila pseudo-obscura*, while Halkka *et al.*¹² inferred strong natural selection at a locus controlling colour polymorphism from exchange of individuals of *Philaenus spumarius* between two island populations. We report here results for the simultaneous perturbation of gene frequencies at three allozyme loci in *Drosophila buzzatii*. The changes in gene frequency following this perturbation provide strong evidence for selection, and for differential selection among the three loci.

The loci chosen for perturbation were *esterase-2* (*Est-2*), *pyranosidase* (*Pyr*) and *alcohol dehydrogenase-1* (*Adh-1*), which are on different chromosomes. The only known chromosome inversions are on the second chromosome¹³, and although *Est-2* is also on this chromosome, its precise relationship to the inversion has not been determined. The alleles whose frequencies were increased were the comparatively rare *Est-2*^c and *Pyr*^b, and the intermediate frequency *Adh-1*^c. At one population in the Hunter Valley, NSW, Australia (locality 5 of ref. 7), wild flies have been collected monthly over a 4-yr period to study temporal changes in gene frequencies. From wild females collected during this temporal study, 37 isofemale lines were made simultaneously homozygous for *Est-2*^c, *Pyr*^b and *Adh-1*^c. These lines were crossed in pairs, then double-crossed and progeny of the latter used to initiate two duplicate population cages.

The population that was perturbed inhabits an isolated clump of *Opuntia inermis* comprising about 40 large plants in an area about 50 × 20 m, and is located some 7 km from the temporal study site. The surrounding area is cultivated or open grazing land, and the nearest *O. inermis* is some 3 km distant. Four estimates of gene frequencies in this population (times 1–4, Fig. 1) were made over 8 weeks before perturbation began. The first

Fig. 1 Changes in gene frequency of *Est-2*^c, *Pyr*^b and *Adh-1*^c during perturbation during times 4–18, and following cessation of perturbation. The dotted line through times 1–4 is the pre-perturbation weighted average gene frequency. Times refer to the sequential number given to each collection and/or release. The gene frequencies plotted are those for non-release flies only, all collected flies that were homozygous *Est-2*^c, *Pyr*^b and *Adh-1*^c being excluded.

Table 1 Post-perturbation phase weighted average migration rates (*m*), range of estimated migration rates over the three loci and heterogeneity χ^2 for different periods

Times	<i>m</i>	Range	χ^2	
18–23	0.827	0.443–0.941	6.671	<i>P</i> < 0.05
18–24	0.951	0.742–1.042	0.898	
18–25	0.883	0.841–1.328	5.412	<i>P</i> < 0.10
18–26	0.990	0.821–1.217	9.162	<i>P</i> < 0.05
18–27	0.855	0.794–1.190	3.867	

release was done at time 4 after collection of flies for gene frequency estimation.

Perturbation was done in two ways. By continuous egg sampling from the homozygous laboratory cages, replicate cages were produced containing all developmental stages from eggs to newly enclosed adults. Two of these were set up in the field every 2–3 weeks, protected against predatory mice and insects and from the direct effects of sun and rain, but with an opening in the lid allowing eclosing adults to escape. Adults entered the population from these cages over a period of 3–6 weeks, depending on the season. In addition, we exploited knowledge of the breeding site of the species. It was thought that, by allowing the immature stages to feed and develop in their natural environment, they might be better adapted to enter the natural population than cage-reared adults. Accordingly, each time that cages were put out in the field, a thick suspension of eggs and young larvae from one to four of the most recently added cage cups was injected into as many rotting cladodes as could be located.

Thirteen such releases were made over 253 d (at times 4–17, excluding time 10). Gene frequency increased significantly at all three loci, but the pattern of change differed for *Est-2*^c and *Pyr*^b compared with *Adh-1*^c. The former initially increased rapidly, remained approximately constant for about 100 d during autumn–winter, and increased again in spring. In contrast, *Adh-1*^c increased steadily through autumn–winter. Selective effects may be implicated as *Adh-1*^c tends to be at higher frequency in the southern part of the species distribution⁷, and its frequency increased among survivors in cold shock experiments (A. W. Watt, personal communication).

After time 18, gene frequencies decreased to approximately pre-perturbation values, but again the patterns of change differed for *Adh-1*^c compared with *Est-2*^c and *Pyr*^b. The latter decreased steadily, but *Adh-1*^c showed a slower and more irregular decrease.

The observed increases in gene frequency during the perturbation phase must have been due to migration into the population of release flies, whereas the decreases in the post-perturbation phase could have been due only to selection or to migration from other populations. For any given time period, if changes in gene frequency were due only to migration, the estimated migration rates for each locus should not be significantly different. However, if there were any differential selection among loci, this could be detected as significant heterogeneity among the estimated migration rates. For each of the perturbation and post-perturbation phases, these migration rates and χ^2 tests of heterogeneity have been estimated¹⁴. During perturbation, migrants were assumed to be release flies only, and the estimated migration rates were not heterogeneous. Weighted average rates for different periods were: pre-perturbation to time 18, 0.458; times 4–18, 0.473; times 5–18, 0.523; times 6–18, 0.375. Thus, some 40–50% of gametes entering the population came from release flies. For post-perturbation, gene frequencies in any migrants are unknown, but were assumed equal to the pre-perturbation weighted average frequencies. Gene frequencies in any migrants from nearby populations are unlikely to be very different; for example, average frequencies in the temporal study population were *Est-2*^c 0.113, *Pyr*^b 0.149, *Adh-1*^c 0.505, as compared with the pre-perturbation weighted average frequencies of 0.120, 0.152 and 0.462, respectively. For the post-perturbation phase, weighted average migration rates

(m), the range of estimated migration rates for each locus and heterogeneity χ^2 for different periods were as shown in Table 1. Given the significant heterogeneity among migration rates and the extraordinarily high rates necessary to account for the changes in gene frequency, migration is not a sufficient explanation for the decreases in gene frequency. Therefore, the post-perturbation decrease of gene frequencies to the pre-perturbation values must be ascribed to natural selection.

We cannot argue from these data that selection has acted directly at the allozyme loci, and two arguments could be raised to suggest that selection may have been acting against chromosome regions marked by these loci. First, although 37 separate lines contributed to the release population, so that its genotype at other than the three loci and closely linked regions should reflect the variability in the natural population from which the lines derived, this latter population was not the one that was perturbed. However, as noted previously, it was only 7 km distant, average gene frequencies for polymorphic allozyme loci were very similar, and it was presumably subject to similar pressures of natural selection. Second, the wild females used to produce the homozygous lines were collected over 6 months, and the time from the middle of this period to the last release at time 17 was 21 months. Adaptation to laboratory conditions during this time may have been such that the post-perturbation effect was one of selection against laboratory-

adapted genomes. Although this is possible, it must be emphasised that during the perturbation phase these genomes were successfully incorporated into the wild population and at least partly recombined with wild genomes. Also, alleles favoured in the laboratory environment but deleterious in the wild should have been largely eliminated during this phase. Finally, there must have been differential selection among the three loci (or among chromosome regions marked by them) to account for the observed heterogeneity in estimated migration rates.

Anaesthetics increase light emission from aequorin at constant ionised calcium

P. F. Baker & A. H. V. Schapira

Department of Physiology, Kings College, Strand, London WC2, UK

The isolation by Shimomura, Johnson and Saiga¹ of a protein, aequorin, that emits light in the presence of micromolar concentrations of ionised calcium opened up new possibilities for the study of ionised calcium inside cells²⁻⁵. It is a relatively simple matter to introduce aequorin into large cells by microinjection, and the rate of light emission gives a direct measure of intracellular free calcium. During an investigation into the action of certain anaesthetics on squid axons, we noticed that these agents always increase the light output from intracellular aequorin. Subsequent analysis has now revealed that this does not result from a rise in ionised calcium inside the axon but seems to reflect a direct effect of the anaesthetic agent on the aequorin molecule. The agents studied all produce greater activation of the light emitting reaction at a constant level of ionised calcium. These rather simple observations have several important biological implications: (1) aequorin might be an interesting model system for studying interaction between anaesthetics and proteins, (2) other Ca-sensitive proteins might behave like aequorin, their affinity for calcium being subject to modulation, and (3) such modulation of endogenous Ca-binding proteins might contribute to the mechanism of anaesthesia.

Figure 1 shows the simultaneous measurement of aequorin light output and calcium efflux from a squid axon. Application of urethane produces a reversible increase in light output which is largely independent of the calcium content of the sea water. The most obvious explanation for this observation is that urethane has, in some way, raised the intracellular ionised calcium concentration, possibly by effecting release of bound calcium. The efflux data of Fig. 1 provide no evidence for such an effect because a rise in ionised calcium should lead to an increase in calcium efflux and the efflux does not change during exposure to urethane.

An alternative explanation consistent with Fig. 1 is that the anaesthetic is not altering intracellular ionised calcium but is

acting directly on the aequorin molecule. This possibility was investigated by introducing aequorin into a 500- μ m diameter porous cellulose acetate tube⁶ and superfusing the trapped aequorin with 0.5 M KCl solution containing 10 mM phosphate, pH 7.2, and a variety of Ca-EGTA buffers. Figure 2 shows that in this *in vitro* assay system urethane still increases light output even when ionised calcium is held constant by a relatively high concentration of calcium buffer. On a log-log plot the effect of urethane is to shift the relationship between light output and ionised calcium to the left without change in slope. As the total light output—assayed by injection of aequorin into a 0.5 M solution of calcium acetate—is not obviously different within the experimental error of about $\pm 5\%$ in the presence of up to

Fig. 1 Simultaneous measurement of aequorin light output (upper trace) and ^{45}Ca efflux (lower trace) during exposure of a cleaned axon of *Loligo forbesi* to urethane and cyanide. Axon 830 μ m; temperature 20 °C. Axon immersed in artificial sea water containing (mM): NaCl, 400; MgCl_2 , 100; CaCl_2 , 10; KCl, 10; NaHCO_3 , 2.5. Calcium was removed for the period indicated. Urethane and cyanide were added to the sea water at the times shown. Note that during the period of urethane application, although the light output increased, calcium efflux was little affected whereas during application of cyanide both light emission and calcium efflux increased roughly in parallel.

200 mM urethane, these observations indicate that urethane is increasing the affinity of aequorin for calcium.

Urethane affects aequorin in the same concentration range as that required to produce anaesthesia. Half-maximal inhibition of the sodium current in squid axons requires about 100 mM urethane⁷. Clear effects of urethane on aequorin can be seen at 20 mM and the increase in rate of light emission is half-maximal also at about 100 mM. Essentially similar results have been obtained with several other anaesthetic agents (Fig. 3). Diethyl ether (100 mM), chloroform (50 mM), ethanol (100 mM), procaine (25 mM), tetracaine (2.5 mM) and althesin increase the light emission by aequorin at constant buffered concentrations of ionised calcium in the physiological range. However, our findings are at variance with those of Kamaya *et al.*⁸, who reported a reduction in calcium-induced light emission from aequorin exposed to a variety of anaesthetic agents. The reason for this difference is not clear. We have only seen inhibition of light output at very high concentrations of urethane and ethanol.

Fig. 2 Effect of urethane on aequorin light output *in vitro*. Continuous measurement of light output from a single sample of aequorin enclosed in a porous cellulose acetate capillary and superfused with test solutions of composition (mM): KCl, 500, potassium phosphate, pH 7.1, 20; Ca-EGTA buffer, 5. *a*, Shows a log-log plot of light output against ionised calcium in the absence (●) and presence (○) of 200 mM urethane. Points were obtained in the order indicated. *b*, Shows light output for a sample of aequorin exposed to 20 and 200 mM urethane in the presence of a Ca-EGTA buffer containing 4 Ca: 10 EGTA. Temperature 20 °C.

These findings are of interest for two reasons. First, we have demonstrated a clear effect of a variety of anaesthetic agents on a well defined soluble protein; this raises once again the possibility that general anaesthesia may result from a direct interaction between anaesthetic and protein in the nervous system. Second, it is possible that other Ca-binding proteins behave like aequorin. It has long been recognised that many intracellular processes are regulated by Ca^{2+} ions. The first to be understood at the molecular level was the regulation of muscular contraction, where the binding of calcium to a low molecular weight protein, troponin C, produces a conformational change that leads to activation of myosin ATPase⁹. More recently, evidence has accumulated that troponin C is only one example of a whole class of Ca-binding proteins (calmodulins) that confer calcium sensitivity on intracellular processes¹⁰⁻¹². The characteristic features of these molecules are a relatively low molecular weight, more than one Ca-binding site and a large conformational change associated with uptake and release of calcium. The resemblance to aequorin is striking and it seems important to establish whether the affinity of these molecules for calcium may be subject to physiological and pharmacological modulation in a manner analogous to that which we have described for aequorin. This could add a further dimension to the already

Fig. 3 Effects of diethyl ether (200 mM, ○) and tetracaine (2.5 mM, ■) on aequorin light output *in vitro*, and light output in the absence of anaesthetic (●). Data from two separate experiments carried out as described in Fig. 2a legend.

complex field of calcium regulation, because not only could reaction rates be altered by changes in free calcium, but they could also be controlled at constant ionised calcium by modifying the affinity of their respective binding sites (calmodulins) for calcium.

To return to the specific case of anaesthesia, anything that increases the permeability of nerve cell membranes to K^+ or Cl^- will render the cells less easy to excite. Both K^+ and Cl^- permeability systems exist in calcium-sensitive forms^{13,14} and Krnjevic¹⁵ has suggested that anaesthetics may activate these systems by producing a rise in intracellular free calcium. The present results suggest an alternative mechanism: anaesthetics may make these calcium-dependent permeability systems more sensitive to calcium, and so reduce excitability without the need for any change in intracellular ionised calcium. This may explain the recent observations of Simons¹⁶ that propranolol increases potassium permeability of human erythrocyte ghosts in which the internal calcium is stabilised by EGTA buffers. In addition to permeability effects, the other calcium-sensitive processes in nerve cells that merit close examination are transmitter release, Ca ATPase and the regulation of cyclic nucleotide levels.

We thank Dr O. Shimomura for the gift of aequorin.

Potassium channels in nodal and internodal axonal membrane of mammalian myelinated fibres

S. Y. Chiu & J. M. Ritchie

Department of Pharmacology, Yale University School of Medicine, New Haven, Connecticut 06510

Horakova *et al.*¹ were the first to observe that the phase of late outward current carried by potassium ions in frog and squid nerve is virtually absent in voltage-clamped rat nodes of Ranvier. This observation has been recently confirmed by Chiu *et al.*² in rabbit nodes of Ranvier, suggesting that the nodal membrane in the mammal generally has few if any potassium channels. The present voltage-clamp experiments show that large potassium currents can, however, be produced in normal rabbit nodes of Ranvier by acute treatment designed to loosen the myelin from the axonal membrane. From this we conclude that whereas potassium channels are absent in the mammalian nodal membrane, they are normally present in the internodal axonal membrane at least in the paranodal region.

Figure 1Ai shows a series of ionic currents (after subtraction of a linear leakage current) obtained in a rabbit node of Ranvier. Starting at an initial holding potential of -80 mV the membrane was clamped to a series of equally spaced potentials in the range -72.5 mV to $+62.5$ mV. The early sodium current is clear in the records whereas there is very little late outward current. Such outward current as was present was quite insensitive to externally applied tetraethylammonium ion (TEA). Various procedures were then applied to loosen the myelin. Typically, the preparation was first exposed to collagenase (Sigma) for 2–10 min to loosen connective tissue. The solution bathing the node was then alternated between normal Locke solution and various modified Locke solutions designed to produce volume changes in the nerve. Three such solutions were used: a Locke solution in which half of the sodium was replaced by potassium, a hypertonic solution produced by adding 0.5 M sucrose to Locke, and a hypotonic solution obtained by diluting Locke with an equal amount of water. These procedures, undertaken in the hope of loosening the axonal membrane from the investing myelins, were repeated several times until a sudden and dramatic increase in the outward current was observed (Fig. 1Bi). Addition of tetrodotoxin (to block the sodium current) left only the outward current (Fig. 2A). External application of 20 mM TEA at this stage usually reversibly reduced the outward current by about 30%. However, when the solution in the end pools was changed from a potassium chloride solution to a caesium chloride (80 mM) and TEA chloride (80 mM) solution the late outward current decreased by about 70% in 10 min (Fig. 2C).

Concomitant with this large increase in outward current was a marked change in the shape of the transient capacity current. Whereas before treatment the initial capacity transient settled quickly in a fraction of a millisecond to a steady state leakage value (first few sampling points after the pulse in Fig. 1Aii), after treatment an additional slow current transient developed with a time constant of 0.5–1.5 ms (Fig. 1Bii). Experiments using hyperpolarising pulses to different potentials between -90 mV and -125 mV showed that this slow current was a linear capacity current. Thus, the time constant of this slow current measured during the pulse was voltage-independent; and it was about the same size as that measured after the end of the pulse. Furthermore, the time integral of this slow current (after subtraction of a steady leakage) obtained during the pulse (that is, the total charge displaced during the on-response) varied linearly with voltage, and roughly equalled that obtained in the off-response following the pulse. We believe that this slow capacity current

occurred because the 'myelin loosening' treatment had exposed a large amount of new axonal membrane previously covered by the myelin, and that the capacity of this newly exposed membrane was now being charged by the voltage-clamp through a large series resistance. For the particular node in Fig. 1, the

Fig. 1 Ionic currents in rabbit node before (Ai) and after (Bi) acute treatment to loosen the myelin. Families of current in both A and B were generated by the same series of depolarisations from an initial holding value of -80 mV to various test potentials in the range -72.5 mV to $+62.5$ mV in 15 mV increments. The currents were corrected for a linear leakage by appropriate scaling of the current response associated with a hyperpolarisation to -125 mV (Aii, Bii). The currents in A were measured in normal Locke after 30 min of repeated treatment (see text). During this period, the outward current and the nodal capacity showed practically no change. Currents in B were measured 3 min after A with the fibre in normal Locke when the late outward current suddenly showed a marked increase. Note that the capacity transient shows both a fast and a slow component; the latter is relatively small beforehand (Aii) whereas afterwards (Bii) it becomes much larger. The nodal capacity was obtained from records Aii and Bii by integrating numerically the capacity current during the pulse after correcting for a steady leakage. Since there were only a few computer sampling points during the fast capacity transient, the value for the capacity obtained by this procedure is based mainly on the slow component of current. The capacity per node obtained in this way was 2.5 pF in A and 35 pF in B. The steady leakage was 2.9 nA in A and 4.4 nA in B. Current signals were sampled every 30 μ s during the test pulse and every 150 μ s afterwards; and the time scale for the current after the pulse had been compressed fivefold compared to that used during the pulse. In addition, the fast capacity transients in A and B were sampled every 12 μ s. C shows the current-voltage relation of the total steady ionic current (mean values ± 1 standard error) for four fibres before (i) and after (ii) acute 'myelin-loosening' treatment (30–45 min). The steady currents were measured 4–8 ms after onset of the potential change. The holding potential was -80 mV for all experiments. The temperature was 24°C .

total capacity suddenly increased from an initial value of 2.5 pF to about 35 pF, with the increase coming mainly from the slow capacity current (see legend to Fig. 1). Interestingly, the dramatic increase in both the outward current and the capacity was not accompanied by a corresponding increase in the early sodium current (Fig. 1A,B), suggesting that the newly exposed axonal membrane has few sodium channels. Figure 1C shows the current-voltage relations of the total late current from four experiments in which both the increase in capacity and the outward current were sudden and particularly marked (the capacity increased by a factor of 20 ± 2.6 from an initial value of 3 ± 1.2 pF).

A simple explanation of these experiments is that the internodal axonal membrane, at least that in the paranodal region, normally contains potassium channels and the nodal axonal membrane does not. This idea is consistent with two recent experiments on mammalian nerve fibres in which the myelin was chronically disturbed by pathological means. First, Brismar³ has shown the consistent presence of potassium currents in alloxan diabetic rats; and it may be relevant that a characteristic of human diabetic neuropathy is a lifting of myelin away from the axonal membrane. Second, in rat dorsal root fibres exposed to diphtheria toxin, Sherratt, Bostock and Sears⁴ have shown that the outward membrane currents in regions of the nerve showing evidence of delayed saltatory or continuous conduction are sensitive to 4-aminopyridine and tetraethylammonium chloride, in contrast to their insensitivity at normal nodes of Ranvier as described by Bostock, Sherratt and Sears⁵. Finally, even in apparently normal nodes, potassium currents have occasionally been observed⁶, perhaps because the paranodal region was exposed by slight mechanical stretching during dissection.

The late outward current reported here is unlikely to be an artefact; and we believe that it is mainly a potassium current for the following reasons. First, it was blocked partially by external TEA and more effectively by allowing caesium and TEA to diffuse to the inside of the node. Second, the time constant of turn-on of this late current was voltage-dependent (as in Fig. 2D), and similar in size to the time constant for potassium

current observed previously in the frog. Thus as Fig. 2B shows the time course of the outward current in Fig. 2A can be reasonably well described by n^4 kinetics in much the same way as in frog fibres⁷. Finally, the outward current showed a reversal potential which became more positive when the external potassium concentration was increased. It seems, therefore, that the biochemical inhomogeneity previously described for sodium channels in mammalian nodal membrane by Ritchie and Rogart⁸ is accompanied by a corresponding complementary inhomogeneity in the distribution of potassium channels. Thus, virtually all the sodium channels are located in the nodal region whereas most of the potassium channels are located in the internodal region. The significance of this uneven distribution of potassium channels remains unclear.

This work was supported in part by a grant NS 12327 from the USPHS and by a grant RG 1162 from the National Multiple Sclerosis Society of the US.

Tumour promoter uncouples β -adrenergic receptor from adenylyl cyclase in mouse epidermis

S. J. Garte & S. Belman

Department of Environmental Medicine, New York University Medical Center, New York, New York 10016

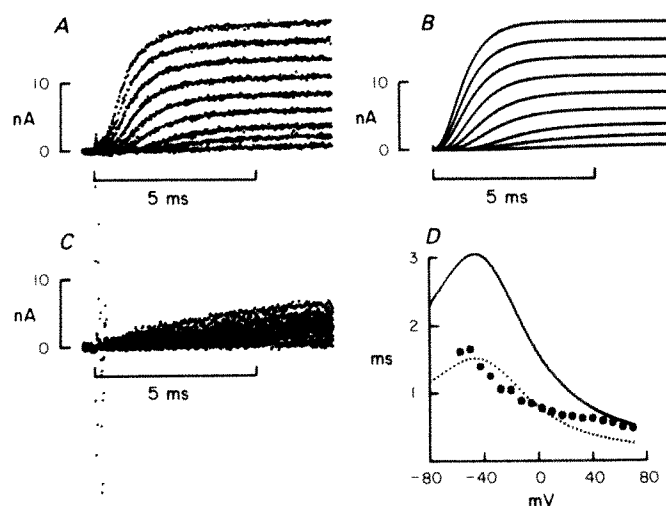

Fig. 2 Kinetics of the late outward current. A shows the effect of applying 100 nM tetrodotoxin on the family of currents in Fig. 1B: the early sodium currents were blocked and only the late outward currents were left. The currents in A were reconstructed in B using the expression $I = I_0[1 - \exp\{-(t - t_D)/\tau_n\}]^4$ with $I = 0$ for $t < t_D$. The voltage dependence of τ_n in the same experiment is shown in D (●). Also shown is the theoretical time constant (solid line) for the frog potassium current at 22 °C using the rate constants from ref. 6; for comparison with the rabbit data this curve has been scaled by a factor of 0.5 (broken line). C shows that the outward current is sensitive to internal Cs and TEA. The records were taken 10 min after changing the end pool solution in A from KCl to 80 mM CsCl and 80 mM TEA-Cl. Temperature, 24 °C.

Alterations in β -adrenergic receptor number and function and in the hormonal responsiveness of adenylyl cyclase have been observed in transformed cells¹⁻³, and tumours^{4,5}. Phorbol myristate acetate (PMA), a potent tumour promoter in mouse skin, induces a dramatic loss of epidermal responsiveness to catecholamines *in vivo*⁶⁻⁸, although basal levels of cyclic AMP are not affected⁷⁻⁹. In other work we have shown that PMA treatment does not alter the number or affinity of epidermal β -receptors, although accumulation of cyclic AMP in response to isoprenaline injection is sharply inhibited¹⁰. Evidence is presented here that PMA exerts this effect by uncoupling epidermal β -receptors from adenylyl cyclase.

Maguire *et al.*¹¹, and Lefkowitz and Williams¹² have established several criteria to distinguish well coupled β -adrenergic receptor-adenylyl cyclase systems from uncoupled or poorly coupled ones. Well coupled adrenergic systems from many cell types and tissues exhibit higher ratios of K_D (dissociation constant for agonist binding) to K_{act} (activation constant or concentration of agonist required to give 50% maximal response) than do poorly coupled systems. Agonist binding is decreased in coupled systems (K_D is increased) by the presence of guanine nucleotides, whereas guanine nucleotides do not affect agonist binding in uncoupled systems. Coupled systems often show lower K_D values and lower Hill coefficients for agonists than do uncoupled systems¹³.

We have measured cyclic AMP accumulation and β -receptor binding by the β -agonist (-)isoprenaline in epidermal homogenates from untreated and PMA-treated mice. Mouse epidermal β -adrenergic receptors have been previously identified and characterised in our laboratory¹⁰, using the labelled

β -antagonist ^3H -labelled (-)dihydroalprenolol (DHA)¹⁴. These receptors exhibit rapid and reversible equilibrium binding, saturability and stereospecificity for the L configuration of antagonists¹⁰.

Female 8-week-old Ha/ICR mice (Sprague-Dawley) were shaved, treated with 10 μg PMA (obtained from P. Borchert, Chemical Carcinogenesis, Eden Prairie, Minnesota) in 0.2 ml acetone or with 0.2 ml acetone alone and killed 12 h later. This interval was chosen because Grimm and Marks have shown the loss of epidermal β -adrenergic responsiveness to be maximal 12 h after PMA treatment⁶. Back skins were removed, stretched on cards epidermis side up, and frozen in liquid N_2 . Epidermis was removed by scraping as previously described⁸. Epidermal homogenates were prepared by homogenisation in a loose Dounce homogeniser (15 strokes by hand) in cold phosphate-buffered saline (PBS), pH 7.2. Agonist binding to homogenates was determined by competition with ^3H -labelled (-)dihydroalprenolol (NEN) as described in the legend to Fig. 3, and cyclic AMP was measured by radioimmunoassay⁸.

Fig. 1 Cyclic AMP accumulation in mouse epidermal homogenates treated with isoprenaline *in vitro*. Pooled epidermal homogenates were prepared from 15 skins as described in the text using 3 ml PBS per epidermis. In 25 ml flasks 2.4 ml of homogenate and 0.3 ml GTP (3 mM) were incubated at 37 °C for 15 min with shaking. Isoprenaline (30 μl) was added for a final concentration of 5×10^{-5} M and the flasks were incubated with shaking at 37 °C for the indicated times, at which point 0.2 ml 100% trichloroacetic acid was added. The flask contents were homogenised in a Polytron, the supernatant was extracted with ether and cyclic AMP was determined by radioimmunoassay as previously described⁸. DNA was determined by fluorometric assay²³. Values shown are means \pm s.e.m. of triplicate points.

Incubation of epidermal homogenates *in vitro* with isoprenaline results in an increase in cyclic AMP levels as shown in Fig. 1. The peak at 10–15 min, followed by a decline is characteristic of the *in vivo* epidermal response to intraperitoneal injection of isoprenaline^{6,7}. Figure 2 illustrates the dose-dependent effect of isoprenaline on homogenates from untreated and PMA-treated mice. The maximal stimulation of cyclic AMP accumulation in PMA-treated epidermis is significantly reduced from controls, and requires 10 times the concentration of isoprenaline. The K_{act} is increased approximately fourfold in the treated group.

Effects of GTP on isoprenaline binding to epidermal homogenates are shown in Fig. 3. The binding and activation data for control and PMA-treated epidermis, are summarised in Table 1.

From these data it seems that *in vivo* PMA treatment of mouse skin eliminates the effect of GTP on K_D and the pseudo-Hill coefficient (k_h) seen in control homogenates. In addition, both binding parameters are increased over controls without GTP. Of primary importance is the large drop (~sevenfold) in the K_D/K_{act} ratio after PMA treatment.

The concentration of isoprenaline required for 50% displacement of the labelled antagonist is considerably ($\sim 10^2$)

Table 1 Isoprenaline binding and activation parameters for untreated and PMA-treated mouse epidermis

	GTP* (300 μM)	Untreated	PMA-treated†
K_D (mM)	–	0.35	0.72
K_D (mM)	+	1.3	0.79
k_h ‡	–	–0.63	–0.85
k_h	+	–0.80	–0.86
K_{act} (mM)§	+	0.39	1.33
K_D/K_{act}	+	4.33	0.60

* GTP present (+) or absent (–) in the incubation mixture.

† PMA (10 μg in 0.2 ml acetone) applied percutaneously 12 h before death.

‡ Pseudo-Hill coefficient (slopes of plots in Fig. 3c, d).

§ K_{act} was determined only in the presence of GTP.

higher than that seen in other β -receptor systems. Not enough is known about the epidermal β -adrenergic system to properly evaluate this discrepancy, although in other work¹⁰ we found that the apparent K_D for antagonist (dihydroalprenolol) binding (52 nM) was also higher than other reported values^{11,12}. Comparably high levels of isoprenaline were required for stimulation of cyclic AMP accumulation as well as for binding. This may be a property of the *in vitro* epidermal preparation and incubation conditions used.

The agonist binding and activation results presented here provide evidence for a β -receptor-adenylate cyclase 'uncoupling' action by PMA. These results are consistent with data obtained using the uncoupling agent filipin^{15,16} and an uncoupled clone of S49 mouse lymphoma¹⁷. Several laboratories have found that incubation of cells with PMA results in a number of cell surface changes^{18–20}. Lee and Weinstein²¹ have shown that PMA interferes with binding of epidermal growth factor to HeLa cell membranes. An uncoupling mechanism for the loss of β -adrenergic responsiveness in mouse epidermis by PMA represents another facet in the action of phorbol ester on plasma membranes.

Fig. 2 Effect of PMA on isoprenaline-stimulated cyclic AMP accumulation in mouse epidermis *in vitro*. Epidermal homogenates were prepared from back skins of untreated (●) or PMA-treated (▲) mice killed 12 h after treatment. Incubation and cyclic AMP determination were carried out as described in the legend to Fig. 1, except that the concentration of isoprenaline was varied as indicated and the time of incubation was 12 min. Values shown are means \pm s.e.m. of triplicates.

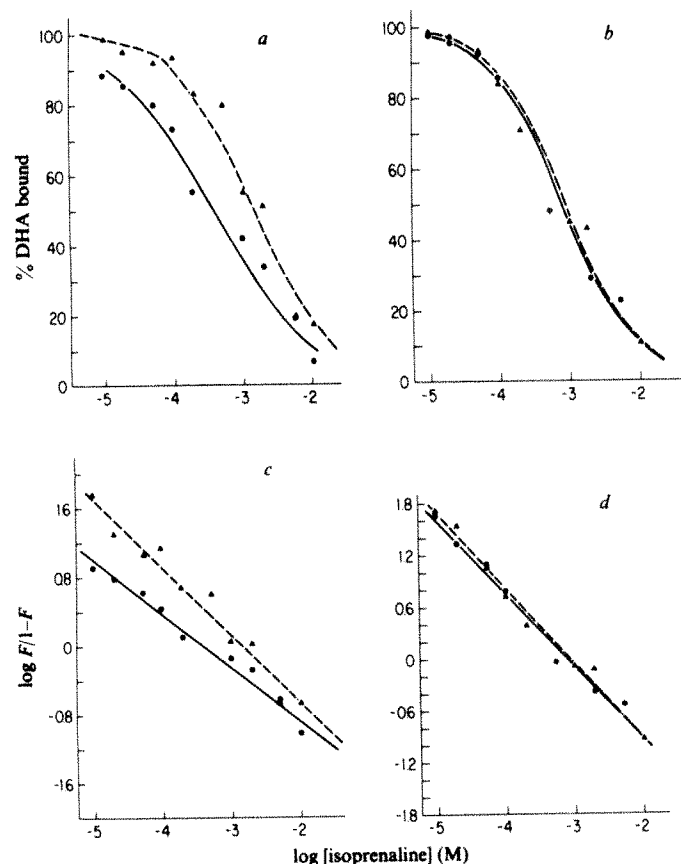

Fig. 3 Effects of GTP on binding of (-)isoprenaline to mouse epidermal β -receptors. Isoprenaline binding was measured by competitive displacement of 3 H-labelled DHA in the presence (▲) and absence (●) of 300 μ M GTP in untreated (a) and in PMA-treated (b) epidermis. Hill plots²⁴ for agonist binding in the presence (▲) and absence (●) of GTP for untreated (c) and PMA-treated (d) epidermis were calculated from the binding data. In triplicate tubes 0.2 ml of epidermal homogenate were incubated at 37 °C in a total volume of 0.5 ml containing PBS, 3 H-labelled DHA (5 pmol, 0.25 μ Ci) and (-)isoprenaline at indicated molar concentrations. GTP (0.15 μ mol) was included in some experiments; (-)propanolol (5 nmol) was added in duplicate tubes for determination of nonspecific binding. After 1 h, binding was terminated by addition of 2 ml ice-cold PBS and tube contents were immediately filtered through GF/D glass fibre filters (Whatman). The filters were thoroughly washed under vacuum with cold PBS, dried, and counted in 10 ml Aquasol (NEN). Counts from tubes containing (-)propanolol were subtracted from total counts to give specific binding. Non-specific binding of DHA represented between 30–50% of total counts. The concentration of DHA used (10 nM) gives 10% saturation of binding sites¹⁰.

Recent work on the β -adrenergic receptor–adenylate cyclase system suggests that the transduction of hormone binding into cyclase activation involves a ‘migration’ of receptors in a fluid membrane²². Phorbol ester, a lipid soluble membrane active compound, may interfere with the transduction or coupling process by altering the fluid or dynamic state of the membrane. The β -adrenergic uncoupling effect demonstrated here may be nonspecific and representative of a general loss or distortion of membrane function (in this case response to hormones) caused by PMA. The significance of the uncoupling effect for tumour promotion *in vivo* is indicated by a correlation between loss of adrenergic response and tumour promoting potency of a number of compounds⁶. An investigation of the coupling efficiency of epidermis undergoing two-stage chemical carcinogenesis and in skin papillomas and tumours is under way.

This investigation was supported by grant CA18536 from the NCI, and is part of a Center Program supported by grant ES00260 from the National Institute of Environmental Health Science and grant CA13343 from the NCI, Department of

Health, Education and Welfare. We thank K. B. Fennikoh for technical assistance.

Host genotype influences immunomodulation by interferon

Edward De Maeyer & Jaqueline De Maeyer-Guignard

Institut Curie, Université de Paris-Sud, Bât. 110, 91405 Orsay, France

Interferon influences both afferent and efferent pathways of delayed-type hypersensitivity (DH) in the mouse. In animals previously sensitised to picryl chloride, sheep red blood cells (SRBC) or Newcastle disease virus (NDV), and treated with interferon just before challenge with any of these antigens, the antigen-elicited reaction, as measured by the ear-swelling (picryl chloride) or footpad swelling (SRBC and NDV) test, is either decreased or completely inhibited, depending on the dose of interferon administered^{1,2}. In addition to this action on expression of the sensitised state, interferon decreases or inhibits sensitisation to SRBC or NDV when administered 24 h before immunisation^{2,3}. These effects were recently confirmed using electrophoretically pure mouse interferon, thus ruling out the possibility that they are caused by other proteins present in the previously used partially purified interferon preparations⁴. For the effect on sensitisation, the timing of interferon administration is crucial, and when interferon is administered a few hours after the antigen, sensitisation can actually be enhanced, as reported here; the enhancement of sensitisation by interferon is influenced by the dose of antigen and by the genotype of the mice that are sensitised.

Sensitisation with sheep erythrocytes was achieved by the method of Lagrange *et al.*⁵. Briefly, mice are sensitised by an intravenous (i.v.) injection of 10^6 SRBC, followed 4 days later by challenge with 10^8 SRBC in 40 μ l of phosphate-buffered saline into the left hind footpad. Footpad swelling is measured 24, 48 and 72 h later with calipers and expressed as the difference in thickness between right (unchallenged) and left foot. Usually, 48-h values are 40–80% higher than 24-h values; at 72 h footpad swelling has significantly decreased.

The interferon used for these experiments was prepared in monolayer cultures of C-243 cells, induced with NDV after priming^{6,7}. It was then purified and concentrated either on blue Sepharose⁸ or on poly (U) Sepharose⁹, giving preparations with a specific activity of $10^{7.5}$ to 10^8 units per mg. For one experiment (Table 1) electrophoretically pure interferon, of specific

Fig. 1 Effect of timing of interferon administration on sensitisation. Three-month-old female BALB/c or C57BL/6 mice were sensitised with 10^6 SRBC. One group of each strain received an intraperitoneal (i.p.) inoculation of 3.3×10^5 interferon units in 1 ml either 24 h before (-24 h), 1 h before (-1 h) or 3 h after ($+3$ h) sensitisation. Footpads were challenged 4 days later; each point represents the 48-h reaction of one animal. See Table 2 for analysis of data.

activity 2×10^9 unit per mg, was used¹⁰. All interferon units are expressed in NIH reference units.

When interferon is given 24 h before immunisation with SRBC, inhibition of sensitisation is more pronounced in BALB/c mice than in C57BL/6 mice, and when it is given only 1 h before SRBC, inhibition of sensitisation no longer occurs in C57BL/6 mice whereas it is still significant in BALB/c mice. These results are summarised in Fig. 1 and Table 2. When interferon is administered 3 h after sensitisation, no significant difference in reaction after footpad challenge is observed between interferon-treated and controls either in BALB/c or C57BL/6 mice, provided they have been sensitised with an optimal dose of antigen (10^6 SRBC) (see also Fig. 1). However, if a sub-optimal dose of antigen is used (10^5 SRBC), a stimulating effect of the subsequent interferon treatment is observed, and this enhancement is more pronounced in C57BL/6 than BALB/c mice (Fig. 2a, Table 2). The difference in reaction to interferon between mice of the two strains is also evident with a dose of antigen that normally does not result in sensitisation. BALB/c mice sensitised with $10^{4.3}$ SRBC and challenged 4 days later do not develop significant footpad swelling, regardless of whether they have been treated with 3.3×10^5 units of interferon 3 h after immunisation. C57BL/6 mice, on the other hand, develop significant footpad swelling if they have been treated with interferon 3 h after immunisation with $10^{4.3}$ SRBC (Fig. 2b, Table 2). Thus, the immunosuppressive effect of exogenous interferon on the afferent pathway of DH to SRBC is more

pronounced in BALB/c than C57BL/6 mice, whereas the immunostimulating effect is more pronounced in C57BL/6 than BALB/c mice.

A striking difference between mice of the two genotypes also exists when the influence of interferon on expression of DH to SRBC is examined. When given a few hours before footpad challenge, interferon inhibits the expression of DH in both strains. However, it is less active in C57BL/6 mice. For example, a dose leading to a pronounced inhibition of footpad swelling in sensitised BALB/c mice remains without significant effect in C57BL/6 mice (Fig. 3, Table 2). About 25 times the amount of interferon used in BALB/c is needed to obtain comparable inhibition of footpad swelling in C57BL/6 (Table 1).

These results have several implications for the immunomodulatory effects of type I interferon. The timing of interferon administration with regard to the time of immunisation is crucial in determining whether inhibition or enhancement of sensitisation will occur. A similar observation was made in a study of the effects of interferon on antibody formation *in vitro*; when interferon is added before the antigen, inhibition of antibody formation is observed, whereas when interferon is added after the antigen, enhancement is sometimes obtained¹¹. In addition to timing, antigen dosage is important, and significant immunoenhancement only results when sub-optimal or normally non-sensitising doses of SRBC are used. In addition to stressing the importance of timing and antigen dose, our results show that immunomodulation by interferon is under the influence of host genotype, as the immunosuppressive effect of interferon on both afferent and efferent pathways of DH to SRBC is less pronounced in C57BL/6 than BALB/c mice, whereas, in contrast, the immunoenhancing effect is more readily obtained in C57BL/6 mice. These observations indicate

Fig. 2 Influence of antigen dosage and mouse strain on enhancement of sensitisation by interferon. Three-month-old female BALB/c or C57BL/6 mice were sensitised by an intravenous inoculation of either 10^5 (a) or $10^{4.3}$ (b) SRBC. The interferon-treated group received 3.3×10^5 units in 1 ml i.p. 3 h after sensitisation. The footpads were challenged 4 days later; each point represents the reaction of one animal, measured 48 h after challenge. See Table 2 for analysis of data.

Table 1 Effect of interferon on expression of DH to SRBC

BALB/c				C57BL/6			
	No. of mice	24-h footpad swelling in 10^{-3} cm units (mean \pm s.d.)	% Of untreated control		24-h footpad swelling in 10^{-3} cm units (mean \pm s.d.)	% Of untreated control	
Controls	6	52.5 \pm 16.0	—	6	65.0 \pm 13.7	—	
Interferon treated

that, in addition to genes influencing the production of interferon^{12,13}, there are genes in the mouse that influence the action of interferon on cells of the immune system; recombinant inbred and congenic lines derived from BALB/c and C57BL/6 mice will be instrumental for further genetic analysis of this phenomenon.

There are other examples of genes influencing interferon action. In the mouse, the *Mx* locus was recently shown to influence interferon action specifically and exclusively on orthomyxovirus replication (O. Haller, personal communication). In man, a gene (or genes) on chromosome 21 influences antiviral activity, and cells trisomic for this chromosome are more sensitive to the antiviral activity of interferon and also to its cell multiplication inhibitory activity¹⁴⁻¹⁶. Recently, a correspond-

ing gene has been localised in the mouse on chromosome 16 (L. Epstein, personal communication, and D. Slate, personal communication). This gene is probably not involved in the effects of genotype interferon action described here because when we compared mouse embryo fibroblast cultures from BALB/c and C57BL/6 origin for their sensitivity to the antiviral effect of interferon as measured by inhibition of VSV replication, no difference was found between the two genotypes (unpublished observations). Different sensitivities to the action of interferon therefore do not seem to be a general characteristic of all BALB/c and C57BL/6 cells. It is more likely that the difference is expressed at the more specialised level of T-cell, B-cell or macrophage function, and *in vitro* experiments comparing cells of both genotypes may clarify this point.

In addition to their theoretical interest, our results have a practical implication. Similar differences in immunomodulation by interferon according to genotype, if found in man, could explain the significant individual variations in the clinical effects of interferon that have been observed.

Fig. 3 Immunosuppressive effect of interferon on expression of DH to SRBC in BALB/c and C57BL/6 mice. The results of three different experiments are combined. Three-month-old-female BALB/c and C57BL/6 mice were sensitised by an i.v. inoculation of 10^6 SRBC. Four days later and 3 h before footpad challenge, the interferon-treated group received an i.p. inoculation of 1 ml containing 3.3×10^5 interferon units (IFa), 3.3×10^4 interferon units (IFb) or phosphate-buffered saline (cont.). Footpad swelling was measured 24 h (a) and 48 h (b) after challenge. Each point represents the footpad swelling of one mouse. The means \pm s.d. of the plotted values are given in Table 2.

Herpes simplex virus depresses antibody production by affecting T-cell function

B. K. Pelton, I. B. Duncan & A. M. Denman

Connective Tissue Diseases Research Group,
Medical Research Council, Northwick Park Hospital,
Watford Road, Harrow, Middlesex, UK

Many viruses enter lympho-reticular cells during pathogenesis and thereby induce immunosuppression¹, which is of practical importance in that it may be related to overall virulence². Immunosuppression may result from a selective infection, as viruses often show an affinity for different lymphocyte subpopulations: Epstein-Barr virus, for example, infects only a small percentage of B cells³. We reported previously that herpes simplex virus (HSV) type 1 suppressed the induction of an antibody response to diphtheria toxoid in cultures of human tonsil cells, and that this seemed to result from the infection of a small percentage of T lymphocytes⁴. However, as fully infectious virus was used in these experiments, it had probably spread from cell to cell in the course of the culture, so complicating the interpretation of the results. Accordingly, we have now re-investigated the mechanism of immunosuppression using temperature-sensitive (*ts*) mutants which fail to complete their growth cycle in the conditions selected for antibody synthesis. In this study, mutants *ts*B, *ts*D and *ts*F, derived from HSV type 1 strain 17, and *ts* 9, derived from HSV type 2 HG 52, were used. The results suggest that the immunosuppression is due to the selective infection by the viruses of helper T cells.

In four experiments a representative example of which is presented in Table 1, the HSV type 1 mutants *ts* B, *ts* D and *ts* F consistently suppressed the synthesis of both specific antibody and immunoglobulin as effectively as did wild-type HSV 1 and HSV 2. In contrast, the HSV type 2 mutant *ts* 9 had little effect. In these experiments, virus was added 24 h after antigen stimulation. Virus assays carried out in all experiments showed that the temperature-sensitive mutants grow in lymphocytes cultured at 31°C but not at the restrictive temperature of 37°C.

Susceptibility to the immunosuppressive effects of the virus was of limited duration, for *ts* F failed to affect antibody synthesis at 37°C when added 72 h or more after induction of the response. This is in keeping with our original observations⁴. After 7 d, the viability of cells in cultures infected with *ts* F, as measured by trypan blue exclusion, was 65% compared with 73% in uninfected cultures, indicating that immunosuppression did not result from an excessive death of lymphocytes.

Table 1 Immunosuppression by *ts* mutants of herpes simplex virus

Virus added	Diphtheria toxoid antibody (U ml ⁻¹)	IgM (μg ml ⁻¹)	IgG (μg ml ⁻¹)
Nil	2.13 ± 0.11	29.5 ± 0.7	57.0 ± 8.4
Type 1 <i>ts</i> ⁺	0.34 ± 0.02	9.8 ± 1.3	25.6 ± 2.1
<i>ts</i> B	0.36 ± 0.02	2.15 ± 0.8	26.5 ± 7.7
<i>ts</i> D	0.45 ± 0.03	9.5 ± 0.7	35.5 ± 3.5
<i>ts</i> F	0.39 ± 0.06	6.8 ± 2.1	37.0 ± 4.9
Type 2 <i>ts</i> ⁺	0.35 ± 0.03	1.9 ± 2.6	36.0 ± 5.6
<i>ts</i> 9	1.45 ± 0.37	24.4 ± 3.1	60.25 ± 3.1

Human tonsil lymphocytes were stimulated with diphtheria toxoid antigen and infected 24 h later with wild-type HSV or *ts* mutants at a multiplicity of infection (MOI) of 0.1 plaque-forming units (PFU) per cell. The cultures were maintained for 7 days at 37°C. The supernatants were assayed for specific antibody to diphtheria toxoid by double antibody radioimmunoassay and for Ig classes by solid phase radioimmunoassay⁴. Values are mean ± s.e.m. of duplicate assays on triplicate cultures from a single tonsil.

The temperature-sensitive block in the mutant *ts* F growth cycle occurs late, allowing the synthesis of structural proteins but not infectious progeny; infected cells could therefore be counted by indirect immunofluorescence in the absence of virus spread. As shown in Table 2, using *ts* F as inoculum, the proportion of infected cells in the population did not exceed 3.2%. Infectious centre assays carried out at 31°C on cultures infected at 37°C with *ts* D or *ts* F which induce immunosuppression and *ts* 9 which does not, showed that less than 1% of the cells supported virus growth. In further experiments, subpopulations of lymphocytes were infected selectively with *ts* F to determine whether the effect on B-lymphocyte activity was direct or indirect. This necessitated a departure from the standardised method described for immunoglobulin synthesis to a micro-culture method using pokeweed mitogen (PWM)⁵, because of the small numbers of cells available after separation. These experiments showed that only in cultures in which T lymphocytes had been infected was immunoglobulin synthesis impaired. In cultures in which uninfected T lymphocytes were cultivated with infected B lymphocytes, immunoglobulin synthesis was not significantly depressed (Table 3). Furthermore, the addition of uninfected T lymphocytes to cultures containing infected T and B lymphocytes, 2 h after mitogen stimulation, partially restored immunoglobulin synthesis (Table 4). Complete restoration was not achieved because the optimal cell concentration for synthesis was disturbed by these manipulations⁶.

Table 2 Per cent tonsil cells infected by *ts* mutants of HSV

Days post-infection		0	1	2	3	7
Mutant	Assay					
<i>ts</i> D	ICA	0.01	0.11	0.014	0.12	0.0
<i>ts</i> F	ICA	0.01	0.10	0.016	0.05	0.0
<i>ts</i> 9	ICA	0.01	0.02	0.013	0.01	0.0
<i>ts</i> F	IF	1.1	3.2	2.1	1.8	1.0

Infectious centre assays (ICA) were carried out on monolayers of baby hamster kidney (BHK) cells. Tonsil cells were infected initially with virus for 2 h at 37°C and cultured in the conditions described in Table 1 legend. Before assay the cells were washed three times in L15 medium, and incubated for 1 h at 37°C in medium containing anti-HSV antibody to neutralise extracellular virus, before washing a further three times in L15 at 4°C. The cells were resuspended at concentrations of 10–10⁶ cells ml⁻¹ in L15 medium containing 0.6% carboxymethylcellulose; 1-ml aliquots were added to BHK monolayers grown in 12-mm diameter, 24-welled plastic plates (Linbro, Flow Laboratories) which were then centrifuged at 300g for 10 min at 4°C. After 3 d incubation at 31°C the plates were fixed with 10% formal saline, stained with crystal violet and the number of plaques counted. Figures are mean of duplicate observations for the percentage of lymphocytes forming plaques. Immunofluorescence (IF) was carried out on cell samples collected daily from bulk cultures. The cells were washed twice in Dulbecco's phosphate-buffered saline, pH 7.4, transferred to Teflon-coated glass slides (Flow Laboratories), fixed in acetone for 15 min at -20°C and stored at -20°C. The preparations were stained with rabbit antisera to HSV type 1 which had been grown in rabbit kidney (RK13) cells, followed by fluorescein-conjugated goat anti-rabbit serum (Behringwerke) and counterstained with rhodamine-conjugated bovine serum albumin (Microbiological Associates). Preparations were mounted in buffered glycerol and examined under a Zeiss microscope (universal) fitted with a Ploem illumination system with separate excitation for the two fluorochromes. Cells were counted in non-overlapping fields until the total number in duplicate samples exceeded 1,000.

As expected, B lymphocytes cultured in isolation failed to synthesise immunoglobulin (Tables 3, 4), indicating that immunoglobulin synthesis in response to PWM is T-cell dependent⁶. The addition of 'T-helper factor' restored immunoglobulin synthesis by isolated infected or uninfected B lymphocytes to an equivalent extent (Table 4). These results confirm that HSV-induced immunosuppression results from a loss of T-helper function.

Table 3 Effect of *ts* mutants of herpes simplex virus on function of lymphocyte subpopulations

Combinations of lymphocyte subpopulations cultured	IgG ($\mu\text{g ml}^{-1}$)
Unseparated	61.75 ± 8.5
Unseparated (<i>ts</i> F)	<3.0
T+B	47.75 ± 4.1
T (<i>ts</i> F)+B	13.88 ± 5.0
T+B (<i>ts</i> F)	32.5 ± 8.48
T (<i>ts</i> F)+B (<i>ts</i> F)	<3.0
B alone	<3.0

Lymphocyte subpopulations were separated by the rosetting method of Gmelig-Meyling and Ballieux⁷. B-lymphocyte preparations obtained contained 98% immunoglobulin-bearing cells⁸, whereas T lymphocytes had $<1\%$. Cultured cells were stimulated with 0.1 ml pokeweed mitogen per 1×10^7 cells at 37°C for 16 h at a concentration of 1×10^6 cells ml^{-1} in Falcon flasks, in a growth medium of RPMI 1640 (bicarbonate buffered), 10% fetal calf serum and 100 U ml^{-1} each of penicillin, streptomycin and mycostatin. The cells were then washed and infected by exposure to *ts* F mutant of HSV at an MOI of 1.0 PFU per cell for 2 h at 37°C . Extraneous virus was removed by washing three times. Cells restimulated by the addition of 2 μl per well of pokeweed mitogen, prepared by standard methods, were cultured in growth medium in wells of microtitre plates at a concentration of 2×10^5 cells per well. The ratio of T lymphocytes to B lymphocytes in recombination experiments were the same as the ratio in the unseparated cultures, namely 1:2. The cells were cultured at 37°C in an atmosphere of 5% CO_2 in air for 7 days. Supernatants were collected and assayed for immunoglobulin by solid phase radioimmunoassay.

Table 4 T cells or T-cell factor restores immunoglobulin synthesis by B lymphocytes exposed to HSV

Combination of lymphocyte subpopulations cultures	IgG ($\mu\text{g ml}^{-1}$)
Expt 1	
T+B	40.0 ± 8.3
T(<i>ts</i> F)+B(<i>ts</i> F)	<3.0
T(<i>ts</i> F)+B(<i>ts</i> F)+T	16.25 ± 2.9
T(<i>ts</i> F)+B(<i>ts</i> F)+T(<i>ts</i> F)	5.0 ± 1.0
Expt 2	
B alone	0.33 ± 0.2
B lymphocytes + T-helper factor	7.4 ± 1.4
B lymphocytes + T-helper factor + HSV	6.6 ± 1.4
T-helper factor alone	<0.01

Expt 1: culture conditions were as described in Table 3 legend. In these cultures, 5×10^4 infected T lymphocytes were incubated with 1×10^5 infected B lymphocytes for 2 h after adding PWM. 5×10^4 of either uninfected or infected T lymphocytes were added. Supernatants were collected after 7 days and assayed for immunoglobulin by solid phase radioimmunoassay. **Expt 2:** 2×10^5 cells were cultured with PWM in microtitre plates for 7 days. B lymphocytes were cultured in a mixture of one part of a 24-h culture supernatant from PWM-stimulated, unseparated cells from the same tonsil and two parts fresh medium. HSV at an MOI of 0.1 was added to the infected cells on day 1 of culture.

Table 5 Failure of ultracentrifuged supernatants from HSV-immunosuppressed tonsil cultures to depress immunoglobulin synthesis in fresh cultures

Culture	IgG ($\mu\text{g ml}^{-1}$)
Immunised	15.5 ± 4.0
Immunised + immunosuppressed supernatant	18.2 ± 5.2
Immunised + control supernatant	22.0 ± 6.5

Supernatants from 7-day-old tonsil cultures immunosuppressed by HSV or from non-immunosuppressed controls were centrifuged at 25,000g for 1 h. New tonsil cells were cultured in the conditions described in Table 1 legend in a mixture of one part of supernatant and two parts of fresh medium. All cultures were assayed after 7 days for immunoglobulin production and virus infectivity. In addition, the original supernatants were tested for infectious virus particles. All virus assays were negative.

We have not detected significant amounts of interferon in cultures of tonsil cells infected with HSV⁴; furthermore, the medium in which infected cells have been cultured and in which free virus has been removed supports normal levels of antibody synthesis by fresh tonsil cells (Table 5).

Our findings indicate that HSV can suppress the antibody response of B lymphocytes to diphtheria toxoid by infecting only a small population of T cells and that this suppression does not depend on a complete cycle of virus replication. Beyond this the mechanism is unclear, for HSV type 1 mutants blocked early (*ts* B, *ts* D) or late (*ts* F) in infection at 37°C were equally immunosuppressive. In contrast, the early-block mutant of HSV type 2, *ts* 9, did not immunosuppress. Because *ts* 9 causes less disruption of host cell metabolism than the other mutants (H. Marsden, personal communication), it suggests that a very early event, such as depression of host cell protein synthesis, may be concerned in the mechanism of HSV-induced immunosuppression.

We thank Professors J. H. Subak-Sharpe and M. C. Timbury for their gift of HSV seed stocks, Dr J. Peutherer for supplying antiviral serum, Mr Ranger and the staff of Mount Vernon Hospital for tonsilectomy samples and Mr T. O. Melbourne for technical assistance.

Lymphocyte differentiation and major histocompatibility complex antigen expression in the embryonic thymus

E. J. Jenkinson, J. J. T. Owen & R. Aspinall

Department of Anatomy, Medical School, University of Birmingham, Edgbaston, Birmingham, UK

During embryogenesis, stem cells migrate from the bloodstream into the thymic rudiment where they proliferate and differentiate into T lymphocytes. The epithelial cells of the thymic stroma may influence these processes by providing hormonal and/or contact stimuli to the developing lymphoblasts^{1,2}. Recently, it has been shown that T cells 'learn' to recognise the major histocompatibility complex (MHC) antigens during thymic lymphopoiesis and become MHC-restricted. Their subsequent response to other antigens can only occur in the context of MHC antigens of the haplotype encountered in the thymus³. Little is known, however, of antigen expression on the thymic stroma which may provide the reference framework on which this MHC restriction is based. In this study we use monoclonal antibodies to show that antigens of the K and I regions of the MHC are detectable on cells of the embryonic mouse thymic stroma from around the 14th day of gestation, just when lymphocyte differentiation is commencing. Furthermore, I-region antigen (Ia antigen) expression is probably limited to thymic epithelium at this stage of gestation and we have not detected Ia on other epithelial tissues of the pharyngeal complex. This pattern of expression is consistent with a role for the thymic stroma in MHC restriction, perhaps by the selection of lymphoid cells for survival on the basis of their recognition of stromal MHC determinants.

Primary cultures of thymus and other tissues removed from CBA/ca (H-2^k), C57BL/10(H-2^b) and BALB/c (H-2^d) embryos were set up in multiwell plates (for details see legend to Table 1). Within 24 h of explantation, cultures were examined for expression of MHC and Thy-1 antigens by an indirect immunofluorescence assay using monoclonal antibodies followed by purified, class-specific, Fab preparations of goat antibodies to mouse IgG₂ or goat antibodies to mouse IgM conjugated with fluorescein or rhodamine (for details see legend to Fig. 1). In this way, the possibility of reactivity to antigens other than those under investigation is minimised and specificity is obtained as evidenced by the complete absence of labelling on control cultures exposed to conjugate alone or where tissues from inappropriate haplotypes are employed. The use of short-term cultures allows unfixed, viable cells to be labelled while avoiding changes in cell populations or cell phenotype that might occur in long-term cultures.

Table 1 MHC and THY-1 antigen expression on embryonic mouse thymus and other organ rudiments

Expt	Age at explantation (d)	Material	Labelling		
			H-2K	H-2I	Thy-1.2
1	13	CBA thymus culture	—	—	NT
		C57BL/10 thymus culture	—	—	NT

3	14	CBA thymus culture	NT	+	NT
		BALB/c thymus culture	NT	—	NT
4	14	CBA thymus culture	+	+	NT
		BALB/c thymus culture	—	—	NT
5	14	CBA thymocyte suspension	NT	—	NT
6	14	CBA thymus culture	+	+	—*
		CBA salivary gland culture	+	—	—
7	15	CBA thymus culture	+	+	—*
		CBA head and neck skin culture	+	—	NT
8	15	CBA thymocyte suspension	+	NT	+
9	15	CBA thymus culture	+	+	NT
		CBA lung rudiment culture	+	—	NT
		CBA thyroid culture	+	—	NT

Embryonic thymus and other organ rudiments were dissected from mouse embryos at 13–15 days of gestation (day of plug = day 0), torn open with watchmakers forceps, washed and incubated at 37 °C for 30 min in 0.25% trypsin. Trypsinisation was terminated by centrifugation through a large volume of RPMI 1640 containing 10% fetal calf serum (RF-10) and the products of 10–15 organ rudiments resuspended in 200 µl of the same medium. Aliquots of cell suspension (40 µl) were placed in the wells of Sterilin immunofluorescence trays and cultured overnight. Suspensions of embryonic thymocytes were obtained just before assay by teasing organ rudiments in a small pool of medium. NT, not tested; +, labelled; —, not labelled.

* Double labelling experiments indicated the presence of some Thy-1.2-positive, Ia-negative cells; see text.

The results summarised in Table 1 indicate that K and I-region products of the MHC cannot be detected on cultured stromal elements of day 13 embryonic mouse thymus, but they are readily demonstrable by day 14 of gestation. The majority of labelled cells are located in cell aggregates and in the outgrowths derived from them (Fig. 1). These aggregates represent portions of thymus incompletely dispersed by the disaggregation procedure. We have examined these cell aggregates by transmission electron microscopy and find that they contain many epithelial cells characterised by tonofibrils and intercellular junctions. In

Fig. 1 Immunofluorescence (a) and phase contrast (b) micrographs of an island of epithelial-like cells in embryonic mouse thymus culture treated with monoclonal anti-Ia antibody. Note punctate fluorescent labelling on cell membranes. c and d, Immunofluorescence and phase contrast micrographs of a similar thymus culture labelled with monoclonal anti-H-2K. Antisera, monoclonal (IgG₂) anti-Ia. 17 (I^k) and monoclonal (IgG₂) anti-H-2K^k (both culture supernatants) used at a dilution of 1 in 4 in RF-20 and monoclonal (IgM) anti-Thy-1.2 (F7D5 ascitic fluid) used at a dilution of 1 in 20 were a generous gift from Drs Beverley and Lake, University College, London. Details of the anti-MHC antisera, which originated from the Department of Genetics, Stanford, USA, coded 10-3.6 and 11-4.1 respectively are given in ref. 9. Fluorescein- and rhodamine-conjugated purified class-specific antibodies to IgG₂ and IgM were a generous gift from Drs Cooper and Lawton, Birmingham, USA and have been described in detail elsewhere¹⁰. Before use on embryonic tissues, monoclonal reagents were checked for specificity and reactivity on adult mouse spleen cells (anti-MHC reagents) and on adult mouse and rat thymocytes (anti-Thy-1.2) (data not shown). Labelling of monolayer cultures were carried out by aspiration of medium from culture wells, addition of 20 µl of antiserum dilution and incubation at 37 °C for 30 min. Wells were washed individually by addition and aspiration of 50 µl of RF-20 followed by addition of 10 µl of rhodamine-conjugated, class-specific Fab preparations of goat anti-mouse IgG₂, fluorescein-conjugated goat anti-mouse IgG₂, or rhodamine-conjugated goat anti-mouse IgM (all at 0.5 mg ml⁻¹) as appropriate. Following 30 min incubation at room temperature, individual wells were washed five times with RF-20, fixed with methanol and a small circular cover slip (Chance no. 0, 6 mm diameter) mounted on 30% glycerol in phosphate-buffered saline was dropped into each well. For simultaneous labelling of Ia and Thy-1 antigens, wells were incubated first with a mixture of anti-Ia and anti-Thy-1 antisera followed by rhodamine-conjugated anti-IgM and fluorescein-conjugated anti-IgG₂. All cultures were examined using a Zeiss Universal microscope with epi-illuminator III/RS, Lamp HB0 50 and standard filter sets 9 or 15.

preliminary studies, using ferritin-conjugated anti-mouse Ig antibody to detect monoclonal anti-Ia antibody binding in the electron microscope, we also find that ferritin labelling of epithelial cells can be demonstrated in the appropriate (H-2^k) strain. In view of these results, it seems likely that many, although not necessarily all, of the aggregate cells expressing K and I-region products from the 14th day of gestation onwards are epithelial cells.

Thy-1-positive cells are detectable within and outside cell aggregates, but in double labelling experiments using anti-IgG₂-fluorescein to detect binding of anti-Ia antibody and anti-IgM-rhodamine to detect binding of anti-Thy-1 antibody, Ia- and Thy-1-positive cells are found to be distinct entities. Suspensions of lymphoid cells prepared by 'teasing' 14-day embryo thymuses are Thy-1 positive, but Ia-negative, when treated with the same reagents. It seems likely, therefore, that most, if not all of the Thy-1-positive cells detected within and outside cell

aggregates are lymphoid cells. Although we cannot exclude the possibility that some thymic stromal cells are Thy-1-positive, as suggested in a previous study using alloantisera on adult thymus cultures⁴, our results do indicate that Ia-positive, embryonic thymic epithelial cells are Thy-1-negative. In this context, it may be noted that the stromal cells of our cultures are heterogeneous since, outside aggregates, long spindle-shaped cells are Ia-negative.

In contrast to cultures of thymus, which express antigens of both K and I regions, epithelial tissues derived from salivary gland, head and neck skin, thyroid and lung rudiments, while expressing K region antigen, do not express Ia. This selective expression of Ia, in the site of T-cell differentiation, strengthens the argument that MHC antigens on thymic epithelial cells play a role in the development of restricted antigen recognition by T cells. In particular, since MHC restriction of the various T-cell subsets involves I as well as K and D-region antigens^{3,5,6}, it would be necessary that thymic epithelial cells express Ia antigens as well as the more ubiquitous K and D-region products from the commencement of lymphopoiesis. The present findings provide direct evidence that this is the case. Further analysis, however, is required to clarify the MHC status of non-epithelial stromal cells which could also contribute to this process. In accordance with our findings in the mouse embryo, the use of heterologous antisera on frozen sections has indicated the presence of Ia-like antigens in the adult guinea pig thymus⁷. Similarly, the expression of K and I region-products on thymic epithelial cells of the postnatal mouse has now been reported⁸.

The precise means whereby interactions between lymphocytes and embryonic thymus stromal cells take place is unclear. In view of the absence of Ia on the differentiating T-lymphoid cells and the corresponding absence of Thy-1 on the thymic epithelial cells, it would seem unlikely that interaction is facilitated by the mutual expression of these surface components on lymphoid and epithelial elements respectively. It is also unlikely that Ia expression on thymic epithelial cells is involved in the process of stem cell migration to the thymus, since migration is initiated some days before we can detect Ia expression. A possible role for epithelial Ia antigen in the initiation of stem cell proliferation following their entry into thymic rudiment is, however, conceivable. Nonetheless, the major function of MHC expression on thymic epithelial cells probably relates to the acquisition of MHC restriction by T cells.

Thus our studies show that K and I-region products of the MHC can be detected on cultures of thymic stromal cells from as early as the 14th day of gestation. While the first lymphoid stem cells probably enter the thymic rudiment from about the 11th day of gestation, the major proliferative burst is occurring from about the 14th day onwards. In the context of MHC restriction, it may be significant that antigens of the MHC regions involved in this process become apparent on the thymic epithelium at this time.

We thank Dr M. Raff for helpful discussions and for the gift of rabbit anti-mouse Ig ferritin, Ms J. Lidstone for help in the preparation of the manuscript and Mr J. Wallington for assistance with the photography and electron microscopy. The work was supported by an MRC grant to J.J.T.O.

V-J joining of immunoglobulin κ genes only occurs on one homologous chromosome

Rolf Joho & Irving L. Weissman

Laboratory for Experimental Oncology, Department of Pathology, Stanford University Medical Center, Stanford, California 94305

In general, heterozygous animal cells express both alleles at a particular locus. The only exceptions are cells of XX genotype after inactivation of one X chromosome¹, and immunoglobulin-producing cells; in each case only one of the two alleles is expressed in differentiated cells and their progeny². This phenomenon, termed allelic exclusion, has been described for several mammalian species including man and mouse. It has been shown that the variable (V) and constant (C) region genes of immunoglobulins undergo a rearrangement during ontogeny^{3,4}. We wished to test whether allelic exclusion in B cells could be the consequence of V- and C-region rearrangement on one of the two homologous chromosomes only. For that reason we chose to analyse the rearrangement of immunoglobulin light chain genes in normal B lymphocytes isolated on the fluorescence-activated cell sorter. We now present evidence that during normal B-lymphocyte differentiation V-C rearrangement occurs only on one chromosome.

In germ-line (sperm) and embryo DNA the variable and constant region genes coding for immunoglobulin heavy and/or light chains are on widely separated DNA segments, whereas in neoplastic plasma cell clones (myelomas) V- and C-region genes are found closer together. Thus, at some point during differentiation of plasma cells (or their B-cell precursors) V- and C-regions are rearranged to form a functional transcription unit. Allelic exclusion could therefore be the consequence of V- and C-region rearrangement on only one of the two chromosomes. The homologous chromosome would not undergo any change and therefore remain silent with respect to expression of the allelic immunoglobulin genes. Restriction fragment analysis of myeloma DNA has led to contradictory results concerning V-C rearrangements on homologous chromosomes: in some myelomas V-C rearrangement seems to have taken place on one chromosome only, as both new V-C gene arrangements and V- and C-containing DNA restriction fragments of the same size as in embryo DNA were found⁵. In other myelomas, only the newly arising restriction fragments carrying the rearranged V and C genes could be detected^{3,4} (R.J., unpublished observation for MOPC 167). This latter finding indicated that both homologous chromosomes might be involved in the translocation process that leads to a functional immunoglobulin gene. As most myelomas are aneuploid tumours carrying several chromosomal aberrations, it is not possible to use them as models for the study of the phenomenon of allelic exclusion.

Figure 1 shows a restriction map of the C_{κ} gene in germ-line and embryo DNA⁶. The C_{κ} gene is close to one end on a

Fig. 1 Restriction map of the C_{κ} gene in germ-line and embryo DNA⁶. The position of the J regions J₁₋₅ is according to Max *et al.*⁷ and Sakano *et al.*⁸. The arrow indicates the direction of transcription. The following restriction enzymes were used: *Bam*HI (Ba); *Bgl*II (B); *Eco*RI (E); *Hind*III (H); *Hpa*I (Hp). kb, kilobase.

13-kilobase *Bam*HI fragment. Five J-region segments had been identified about 2.5–4.0 kilobases from the 5' end of the C_κ gene^{7,8}. Analysis of κ -chain clones from myeloma DNA had revealed that the 3' end of the V_κ to be expressed (including its 5'-flanking sequence⁹) was joined to the 5' end of a J region^{5,8}. Comparative analysis of restriction fragments of embryo and myeloma DNA resulted in restriction fragments of different sizes. The restriction enzyme *Bam*HI seemed to be a good choice for allowing V–J joining, because this event should always alter the 13-kilobase *Bam*HI fragment and create a V_κ - and C_κ -bearing *Bam*HI fragment of a different size. In fact, all κ -producing myelomas so analysed show new *Bam*HI fragments containing V_κ and C_κ sequences^{3–5}. Each new restriction fragment created by V–C translocation could differ in size from one lymphocyte to the other depending on which variable region has joined with which J region. As there are a large number of germ-line V_κ genes, *Bam*HI restriction fragment analysis of κ -light chain-producing cells does not necessarily show any particular new fragments, because the specific rearrangement of each lymphocyte would not be detected in a heterogeneous population of κ -bearing B cells. If V–C region rearrangement involved both homologous chromosomes, a disappearance of the 13-kilobase *Bam*HI germ-line fragment should be seen. However, if this event occurs on one chromosome only, the 13-kilobase *Bam*HI fragment should be retained.

We isolated splenic B lymphocytes having surface κ light chain. Staining of spleen cells with rabbit anti- κ immunoglobulin (Ig) and fluorescent goat anti-rabbit Ig antibodies yielded two different populations of cells. About 50–55% of spleen cells gave positive fluorescence when stained with a

rabbit anti- κ Ig whereas the remaining 45–50% did not stain above background (controls for background were the same cells stained at the same concentration with rabbit anti-keyhole limpet haemocyanin antibodies and the fluorescent goat anti-rabbit Ig). These two populations were purified on the fluorescence-activated cell sorter¹⁰. We isolated κ -positive (κ^+) from κ -negative (κ^-) cells. To minimise contamination, cells weakly positive for κ were not sorted as κ^+ cells. Contamination of sorted κ^+ with κ^- cells was less than 4%. DNA of κ^+ cells were purified, digested with *Bam*HI and electrophoresed through agarose to separate the resulting restriction fragments. After transfer of the DNA to DBM paper¹¹, restriction fragments bearing κ -region genes were detected by hybridisation with a nick-translated plasmid containing a purified C_κ -region insert⁶.

Table 1 Relative band intensities of various DNA digests

DNA digest	Relative band intensity	
	C_κ	Ribosomal
5 μ g <i>Bam</i> HI sperm	85	245
10 μ g <i>Bam</i> HI sperm	172	561
10 μ g <i>Bam</i> HI κ^+	87	664

The relative band intensities were determined by densitometry. Analysis of *Bam*HI-digested DNA with CD18 was used as internal standard and the intensities of all bands per lane were added up.

Figure 2 shows the results of this experiment. DNA from κ^+ cells is compared with different amounts of sperm DNA. The 13-kilobase *Bam*HI germ-line fragment is clearly detectable in κ^+ DNA. We interpret this to demonstrate that both homologous chromosomes have not undergone a rearrangement with respect to their V_κ and C_κ genes. If V–J joining takes place on one chromosome one would expect a 13-kilobase *Bam*HI fragment of half the intensity compared with the same amount of germ-line (sperm) DNA. To control for possible inaccuracies in the determination of the input DNA amounts, the band intensities were compared with an internal standard. For this, the DBM paper was washed in 0.4 M NaOH for 30 min, neutralised and rehybridised to a ³²P-labelled plasmid containing a ribosomal DNA insert¹². These results are shown in Fig. 2 and summarised in Table 1. The intensity of the ribosomal bands of 10 μ g sperm and 10 μ g κ^+ DNA after *Bam*HI restriction is the same. However, the intensity of the 13-kilobase C_κ fragment of 10 μ g κ^+ DNA corresponds to that of the 5 μ g sperm DNA. This is in agreement with the idea that V–C joining occurs on one chromosome during differentiation of κ -chain-expressing B lymphocytes. These experiments clearly demonstrate that in the majority of B cells V–J joining and therefore the formation of a functional transcription unit for κ chains does not occur on both chromosomes. However, a small fraction of B cells could have undergone V–J joining on both chromosomes and would not have been detected by this assay. We speculate that the consequence of V–J joining on one chromosome is the allelic exclusion of immunoglobulin gene products in B cells and plasma cells. Given that allelic exclusion may result from differential V–J joining, one must consider potential molecular mechanisms for this event. A reasonable assumption is that differentiating lymphoid cells of the B-cell lineage contain some highly specific enzymes that accomplish the V–J joining. It is not clear how these putative recombinases (or other enzymes effecting V–J joining) use only one of two identical chromosomes as their substrate and leave the second (homologous) one unchanged. Several possible mechanisms could lead to the activation of immunoglobulin genes on one chromosome only. One can imagine the production of one essential enzyme molecule (either the recombinase or a molecule that renders the chromosome susceptible to recombinase action) per cell that works in a stoichiometric fashion—one molecule per chromosome. Once V–J joining has been initiated the enzyme molecule is no longer active. Differentiating lymphoid cells that do not produce this enzyme would not enter the B-cell lineage.

Fig. 2 A spleen cell suspension from BALB/c mice was treated on ice with 10 vol 8.3 g l⁻¹ NH₄Cl and 1 g l⁻¹ KHCO₃, pH 7.4, to lyse erythrocytes. The nucleated cells were collected by centrifugation, washed, stained with 40 μ g ml⁻¹ rabbit anti-mouse κ antibodies and counterstained with 75 μ g ml⁻¹ fluorescent goat anti-rabbit Ig antibodies. About 55% of the cells stained with the anti- κ antibodies. The brighter 50% of the spleen cells were sorted on a fluorescence-activated cell sorter⁹ (FACS III, Becton Dickinson). On re-analysis, this population was about 96% κ^+ . DNA was purified and analysed with *Bam*HI as described elsewhere⁶. The restriction fragments were electrophoresed through 0.7% agarose and transferred to DBM-paper¹⁰. Hybridisation was to ³²P-labelled C_κ probe (lanes a–d) or a plasmid containing a *Xenopus laevis* ribosomal DNA insert (CD18)¹¹ (lanes e–h). a, e, 1 μ g sperm DNA; b, f, 5 μ g sperm DNA; c, g, 10 μ g sperm DNA; d, h, 10 μ g κ^+ DNA. The molecular weight standard is *Hind*III-digested λ DNA.

A slightly different possibility is that a limiting amount of the enzyme is produced. If the enzyme level is too low no V-J joining occurs, and these cells will not become B lymphocytes. At higher enzyme levels one chromosome can be activated, leading to immunoglobulin-producing cells. At still higher levels (or infrequently at low enzyme levels) one would expect a rearrangement of V and C genes on both chromosomes in a small subpopulation of differentiating cells. This could lead to death of those cells if the V-C interval contains gene(s) essential to cell viability, and if this interval is excised during differentiation. A third possibility would be that as soon as rearrangement has been initiated a negative feedback prevents new rearrangements from taking place. Whatever the situation, selective chromosomal expression in the case of the κ chain accompanies selective chromosomal rearrangements. In

contrast, X-chromosomal allelic exclusion is apparently the consequence of selective chromosomal inactivation¹³. Nevertheless, it is possible that both activation and inactivation of chromosomal segments may result from selective irreversible chromosomal rearrangements.

We thank Ann Adey for technical assistance, Dr Robert Coffman for the gift of antibodies and his advice for cell staining and sorting, and Dr Leonard Herzenberg for reviewing the manuscript. R.J. is a special fellow of the Leukemia Society of America and I.W. is the recipient of an American Cancer Society Faculty Research Award. This work was supported by grants from the USPHS and the ACS with the initial part of this project being supported by a fellowship of the "Schweizerischer Nationalfonds" to R.J.

Changes in the structural organisation of chromatin are necessary for the progression of the cell cycle. These changes are thought to be regulated mainly by the modification of chromosomal proteins by reactions such as phosphorylation¹⁻⁸, acetylation⁹⁻¹², methylation^{13,14} and poly(ADP-ribosylation)^{15,16}. Among these modifications, phosphorylation of histones, especially that of the H1 histone, is the most likely candidate for a factor which regulates chromosome condensation¹⁻⁸. It has been proposed that the phosphorylated form of H1 histone may be involved in the initiation of chromosome condensation¹⁻⁴ or in the maintenance of the condensed state of chromatin⁸. The latter possibility is unlikely because zinc chloride, which inhibits phosphatase *in vivo* and preserves the highly phosphorylated form of H1 histone at metaphase, does not prevent the dispersion of chromosomes at the end of mitosis¹⁷. As for the former possibility, Bradbury *et al.* reported² that the activity of H1 histone phosphorylation is closely correlated with mitotic triggering in the cell cycle and suggest^{3,4} that H1 histone phosphokinase is involved in the initiation of mitosis. However, no causal relationship has been established. To analyse the mechanism of the progression of the cell cycle, we have isolated several temperature-sensitive (ts) growth mutants from FM3A, a cell line derived from C3H mouse mammary carcinoma¹⁸. We report here on one of these ts mutants, designated the ts85 strain, which shows an abnormal chromosome condensation as well as deficiency in H1 histone phosphorylation at the non-permissive temperature. Our results support the hypothesis that H1 histone phosphorylation controls the initiation step of mitosis through chromosome condensation.

The ts85 cells were obtained as follows. Logarithmically growing FM3A cells in suspension culture were treated with 0.3 $\mu\text{g ml}^{-1}$ N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) for 16 h at 33 °C and incubated for 3 days of expression time. Wild FM3A cells were killed by the addition of ³H-thymidine (15 Ci mmol⁻¹ 5 $\mu\text{Ci ml}^{-1}$) for 16 h after the cells had been shifted up to 39 °C, the non-permissive temperature for ts cells. The selection schedule was repeated several times and then the surviving cells were inoculated into soft agar plates^{19,20} and incubated at 33 °C (permissive temperature) for about 2 weeks. The colonies which developed were checked for growth at 33 °C and 39 °C. The ts85 was one of the clones which showed no increase in the cell number at 39 °C but normal growth at 33 °C.

The ts85 cells were synchronised at the G1/S boundary by double treatment with excess thymidine at 33 °C and then permitted to enter the S phase at 33 °C or 39 °C. The amount of DNA synthesised at 39 °C was almost the same as that at 33 °C, but no mitotic cells were detected at 39 °C (Fig. 1), indicating that at the non-permissive temperature ts85 cells were arrested before the mitotic phase. When ts85 cells growing logarithmically at 33 °C were shifted up to 39 °C and incubated for 16 h, using a cytofluorometer, most of the cells were found to be arrested at the G2 phase. Details of the growth characteristics of ts85 will be reported elsewhere²¹.

To determine whether or not ts85 cells contain condensed chromatin at the arrested state at 39 °C, electron microscopic observations were carried out. As shown in Fig. 2, a small fraction of the chromatin was condensed into a fragmented form (arrow in Fig. 2), but the structures of the nuclear membrane and nucleoli were preserved. The incomplete condensation was observed in 80% of the total population after incubation for 16 h at 39 °C. Thus, most of the chromatin did not initiate condensation at the arrested state and as a result, the cells were not able to enter the mitotic phase.

If H1 histone phosphorylation stimulates the initiation of chromosome condensation¹⁻⁸, cells with a defect in chromosome condensation might have a deficiency in H1 histone phosphorylation. This is the case with ts85 cells. These cells were synchronised at the G1/S boundary, released from the blockade, incubated at 33 °C or 39 °C and the phosphorylation pattern of the histones was examined. Figure 3 shows the incorporation of ³²P and the densitometric profile of histones isolated from G2, M phase cells and cells arrested at 39 °C. The rate of phosphorylation at 39 °C of the H1 histone decreased to 1/10th of that at 33 °C (Fig. 3). The rates of phosphorylation of H2A and H4 histones, however, were somewhat higher at 39 °C

*Present address: Department of Pharmacology, Keio University School of Medicine, Shinanomachi, Tokyo, Japan.

Fig. 1 DNA synthesis and entry into mitosis after synchronisation at the G1/S boundary. Logarithmically growing ts85 cells in suspension were treated with excess thymidine (2 mM) in RPMI-1640 containing 10% dialysed calf serum at 33 °C for 18 h. After removing excess thymidine, cells were incubated at 33 °C for 8 h in normal medium, then the second treatment with excess thymidine for 10 h at 33 °C was given. The ts85 cells which accumulated at the G1/S boundary were permitted to enter the S phase at 33 °C or 39 °C in normal medium containing 0.03 $\mu\text{g ml}^{-1}$ colcemid (Ciba). DNA synthetic activity at 33 °C (○) or 39 °C (●) was measured by pulse labelling with ^3H -deoxyadenosine (AdR, 1 $\mu\text{Ci ml}^{-1}$, 21 Ci mmol $^{-1}$) for 30 min at each temperature. The alkaline-resistant radioactivity in acid-insoluble materials collected on Whatman glass fibre filters (type GF/C) was measured by liquid scintillation spectrometer. Mitotic index at 33 °C (□) or 39 °C (■) was measured by microscopic observation of cells treated with 1% sodium citrate and fixed with methanol/acetic acid (3:1 v/v).

Fig. 2 Electron microscopic observation of a ts85 cell possessing fragmented abnormal condensation of chromatin (indicated by arrow) in the nucleus at 39 °C. Logarithmically growing ts85 cells at 33 °C were incubated at 39 °C for 16 h. After incubation, the cells were washed with 0.1 M phosphate buffer (pH 7.4) and fixed with phosphate-buffered 2.5% glutaraldehyde (pH 7.4) for 1 h at room temperature. After a wash with the same buffer, cells were post-fixed with 1% osmium tetroxide in the same buffer for 1 h at room temperature. The fixed cells were embedded in Epon-Araldite, cut into thin sections using a Sorvall ultramicrotome and observed with a JEOL 100B transmission electron microscope operated at 80 kV. In wild-type cells at both temperatures and ts85 cells at 33 °C, no such fragmented abnormal condensation of chromatin was detected throughout their cell cycles.

Fig. 3 The profile of phosphorylation of histones of ts85 cells at the permissive and non-permissive temperatures. The ts85 cells were synchronised at the G1/S boundary as described in Fig. 1 legend. When the cells were released from the blockade and entered the S phase, they were pulse labelled with ^{32}P -ortho-phosphate ($100\ \mu\text{Ci ml}^{-1}$, carrier free) for 2 h at 6 and 13.5 h after release from the blockade, corresponding to the G2 and M phases at 33 °C. The ts85 cells arrested at the G2 phase at 39 °C were labelled at 13.5 h. Histone fractions were extracted as follows. Cells frozen at -20 °C ($5\text{--}10 \times 10^6$ cells) were thawed and suspended in 1 ml of hypotonic buffer T (10 mM Tris-HCl, pH 7.8, 2 mM MgCl_2 , 0.5 mM EDTA, 2 mM 2-mercaptoethanol and 0.025% Triton X-100). After standing for 10 min at 4 °C, they were homogenised by 15 strokes with a Teflon pestle glass Potter Elvehjem homogeniser and centrifuged at 800g for 5 min. The precipitate was washed successively with buffer T, buffer A (50 mM Tris-HCl, pH 7.4, 0.14 M 2-mercaptoethanol and 50 mM sodium bisulphite) and buffer A containing 0.15 M NaCl, with stirring. Nuclei were pelleted at 12,000g for 10 min. Histones were then extracted by 0.4 N sulphuric acid for 1 h with stirring at 4 °C. Histones obtained were pelleted by 18% trichloroacetic acid and washed once with acetone-HCl (HCl 0.5% v/v) and twice with acetone. They were analysed by acid urea 15% polyacrylamide gel electrophoresis (0.9 N acetic acid-2 M urea, 25 cm gel) according to the method of Panyim and Chalkley²³. After electrophoresis for 30 h, the gels were stained with Coomassie brilliant blue R and were scanned with a densitometer. Gels were frozen at -80 °C and cut into 1.2-mm slices. Each slice was put into a vial, solubilised with Soluene 350 (Packard) and the radioactivity measured by a liquid scintillation spectrometer using toluene-based scintillation fluid. *a*, G2 phase at 33 °C; *b*, G2-arrested at 39 °C; *c*, M phase at 33 °C. A densitogram is shown under the profile of each phosphorylation pattern. X was the unknown protein which existed in wild-type cells and ts85 cells at both temperatures. The peaks which appeared in the densitogram, from left to right, correspond to H1, H3, H2B, H2A and H4 histone, respectively.

than at 33 °C. The highly phosphorylated form of the H1 histone which was detected in M phase cells (indicated by arrow C in Fig. 3c) did not exist in the G2-arrested cells at 39 °C. It has been reported that when the synthesis of histones is blocked by an inhibitor of DNA synthesis⁷ or X-ray irradiation²², the phosphorylation of all the histones is apparently reduced. In the ts85 cells, the amount of histones synthesised at 39 °C was 85% of that at 33 °C and the synthesis of H1 histone was not specifically inhibited at 39 °C. Furthermore, a band behind the H1 histone subfractions (as shown by arrow A in Fig. 3), was found at 33 °C but not at 39 °C. This protein is insoluble in 5% perchloric acid (PCA) and extracted by 0.2 M sulphuric acid. The role of this protein is unknown but it may be related to chromosome condensation. The specific decrease in the rate of H1 histone phosphorylation and the absence of the highly phosphorylated form of H1 histone at 39 °C did not result from cessation of the cell cycle at the G2 phase, because the rate of H1 histone phosphorylation remained constant throughout the S to M phases in both wild-type cells and grow-revertant ts85 cells. Other ts mutants (ts18 of FM3A cells, 11C3 of CHO cells) which were also arrested at the G2 phase at 39 °C had no defects in H1 histone phosphorylation (unpublished data).

Figure 3 also shows that H3 histone (indicated by arrow B) was not phosphorylated at 39 °C, whereas at 33 °C ts85 cells entered the mitotic phase and marked H3 histone phosphorylation occurred^{5,7,8}. This lack of H3 histone phosphorylation may be due to the cessation of the cell cycle, that is, ts85 cells may have been arrested before the onset of the mitotic phase.

The above data suggest that the phosphorylation of H1 histones is one of the factors involved in the initiation of chromosome condensation and the low level of H1 histone phosphorylation may induce incomplete condensation of the chromatin.

We thank Mr S. Kondo for help in the electron microscopic observations. This work was supported in part by a Grant-in-Aid for Cancer Research from the Ministry of Education, Science and Culture, Japan, and by a Life Science grant from the

Institute of Physical and Chemical Research, Tokyo, Japan. S.M. was a visiting graduate student to Mitsubishi-Kasei Institute of Life Sciences during part of this work.

The relationship between coding sequences and function in haemoglobin

William A. Eaton

Laboratory of Chemical Physics, National Institute of Arthritis, Metabolism and Digestive Diseases, National Institutes of Health, Bethesda, Maryland 20205

Gilbert has suggested that the presence of intervening sequences in DNA, called introns, can speed evolution by allowing novel proteins to be constructed from the pieces of existing ones¹. This hypothesis further suggests that the coding sequences, called exons, correspond to functional parts of the protein. The most striking example so far is the case of the immunoglobulin γ heavy chain, where the four polypeptide sequences corresponding to the four coding sequences form structurally and functionally distinct parts of the molecule^{1,2}. The relation between the three coding sequences of the β globin gene and structure or function is not as obvious, but the central coding sequence does code for the part of the globin chain which forms the haem crevice^{3,4}. To further test the idea that coding sequences correspond to functional units of proteins we consider the relationship between the coding sequences of α and β globin genes and the corresponding parts of the complete, tetrameric haemoglobin molecule.

The principal function of haemoglobin in vertebrates is to transport oxygen. Haemoglobin performs this function effectively by binding oxygen cooperatively, and with an overall affinity appropriate to physiological conditions. The affinity is regulated by protons and carbon dioxide (the Bohr effect), and by organic phosphates (2,3-diphosphoglycerate (DPG) in mammals). According to the simplest allosteric model for cooperative behaviour⁵, haemoglobin exists in two affinity states, corresponding to the quaternary structures of oxyhaemoglobin (R state) and deoxyhaemoglobin (T state). Binding within either the T or R state is noncooperative. Cooperativity is achieved by switching from the low affinity T state to the high affinity R state as successive molecules of oxygen bind. Regulation of oxygen affinity is achieved by the preferential binding of protons, carbon dioxide, and organic phosphates to the low affinity T state. The difference in tertiary conformation within

each quaternary structure produces a difference in affinity of the haems for oxygen. The model is somewhat oversimplified, but provides a good first order description of functional properties and a useful framework for correlating structure with function⁶⁻¹¹.

The large number of investigations on structure-function relationships in haemoglobin, which were pioneered by the work of Perutz and coworkers, make it possible to assign well defined functional roles to individual amino acid residues^{6,12,13}. From inspection of the three-dimensional structure of human haemoglobin, five functional categories are apparent^{6,11,14-16}.

(1) Residues in contact with the haem. These residues provide the hydrophobic environment necessary for the haem to be oxygenated by oxygen, rather than be oxidised. Haem contact residues also transmit structural changes, caused by oxygenation at the haem, to the $\alpha_1\beta_2$ subunit interface. (2) Residues in the $\alpha_1\beta_1$ contact. When haemoglobin switches quaternary structure, the $\alpha_1\beta_2$ intersubunit bonding is altered, but the same residues are involved in both quaternary structures. (3) Residues in the $\alpha_1\beta_1$ contact. This contact remains unaltered by the quaternary structure change. (4) Residues of the β chain that bind DPG. (5) Residues involved in the Bohr effect. As protons are not resolvable in the X-ray electron density map of haemoglobin, these residue assignments require detailed consideration of both the structure and solution chemistry^{6,11,17}.

Functional studies on haemoglobin variants provide support for the residue assignments. The functional residues, together with the known variants of human haemoglobin^{18,19} are listed in

Fig. 1 Residues with well defined functional roles in human haemoglobin and α and β variants. For each chain, positions are marked for those residues that belong to one of the five categories discussed in the text. Haem contact, $\alpha_1\beta_2$ contact, and $\alpha_1\beta_1$ contact residues for deoxyhaemoglobin are taken from Fermi¹⁴. Haem contact, $\alpha_1\beta_2$ contact and $\alpha_1\beta_1$ contact residues for human carbomonoxyhaemoglobin, defined as a residue containing at least one atom within 4 Å of a haem atom or adjacent subunit atom, were calculated from the coordinates deposited by Joyce Baldwin with the Brookhaven Protein Data Bank. DPG binding site residues are taken from Arnott¹⁶; and Bohr effect residues are taken from Baldwin and Chothia¹¹ and Matthew *et al.*¹⁷. Carbon dioxide binds to α -amino groups of both α and β chains. Above the functional residues list are the number of variants at each residue position with known abnormal properties *in vitro*, and below the functional list are the number of variants at each residue position with no known abnormal properties *in vitro*. For the most part, the variants have not been studied in great detail. It is, therefore, likely that some variants listed as normal may exhibit functional impairment when examined further. The list of haemoglobin variants is published in the journal *Hemoglobin*^{18,19}.

Fig. 1. Among α chain variants with known abnormal properties *in vitro*, 77% (17 out of 22) contain substitutions at one of the functional residue positions, while 83% (48 out of 58) of the variants with no known abnormal properties *in vitro* contain substitutions at 'non-functional' residue positions. Among β chain variants the corresponding values are 63% (66 out of 104) and 83% (49 out of 59). If clinical findings are used as criteria, all four percentages are higher^{12,29}. These statistics support the relative significance of the residues in the five categories, but also suggest that functionally significant residues are missing from the list. For example, there are additional residues in the interior of the protein that maintain the stability of the three-dimensional structure, and additional residues that undergo conformational changes as part of the cooperative binding mechanism^{11,20}. Also, residues on the haemoglobin surface function to prevent aggregation of tetramers (as occurs in sickle cell disease) at the high concentrations found in the red cell²¹. Residue assignments for these functions cannot at present be made with confidence.

The residues associated with each of the five functions are listed in Fig. 2, which also shows their distribution in relation to the three coding sequences of the α and β globin genes. First, as pointed out by Blake³ and Gibert⁴, most of the residues (16 out of 20) in contact with the haem correspond to the central coding sequence of the β globin gene. In the α gene, 16 out of 20 of the haem contact residues are also contained in the central sequence. The distribution of intersubunit contacts among the three coding sequences shows a very strong correlation as well. In the case of the $\alpha_1\beta_2$ contact, the central sequence contains 12 out of the 15 residues in the β subunit that form intersubunit bonds, and 13 out of 18 residues in the α subunit. For the $\alpha_1\beta_1$ contact the third sequence contains 13 out of the 18 intersubunit bonding residues in the α subunit, and 14 out of 18 in the β subunit. The distribution of residues involved in binding the regulators—protons, carbon dioxide, and DPG—indicates no marked correlation, although the most important residues are contained in the first and third sequences.

The distribution of functional residues among the three coding sequences suggests that coding sequences do correspond to the major functions of haemoglobin. It is therefore interesting to speculate on the possible role that coding sequences played in the evolution of haemoglobin. One possible evolutionary pathway for mammalian haemoglobin is the following. The primitive haemoglobin is assumed to be a monomeric protein, capable of reversible oxygen binding, and coded for by a gene containing three separate coding sequences. Following gene duplication point mutations in the central coding sequence of the primitive α and β globin genes led to the development of the $\alpha_1\beta_2$ dimer that was capable of cooperative oxygen binding. (Note that lamprey haemoglobin, which has previously been considered to behave as a possible intermediate in the evolution of haemoglobin tetramers from monomers^{26,27}, is a monomer when oxygenated. It achieves cooperativity by aggregating in the deoxy state to form a homodimer, which is very probably of the $\alpha_1\beta_2$ type^{26,27}.) The maximum Hill n value for such a dimer was 2. An increase in cooperativity toward the current n value of 2.8 to 3.0 took place with the evolution of the $\alpha_1\beta_1$ contact to form a tetramer. The concentration of $\alpha_1\beta_1$ contact residues in the third sequence suggests that the third coding sequence in the α or β globin gene (or both) replaced its predecessor by recombination, thereby speeding the evolutionary process. The most recent events of evolution involved development of the Bohr effect and DPG binding residues, which are responsible for fine-tuning haemoglobin function. The almost complete absence of haem or intersubunit contacts in the first polypeptide sequence makes it conceivable that the corresponding coding sequence also replaced the preceding one in both α and β globin genes by recombination, thus more rapidly completing the evolution of the regulation of oxygen binding by protons, carbon dioxide, and DPG.

Considerations of haemoglobin evolution from amino acid sequence comparisons among species do not appear to argue

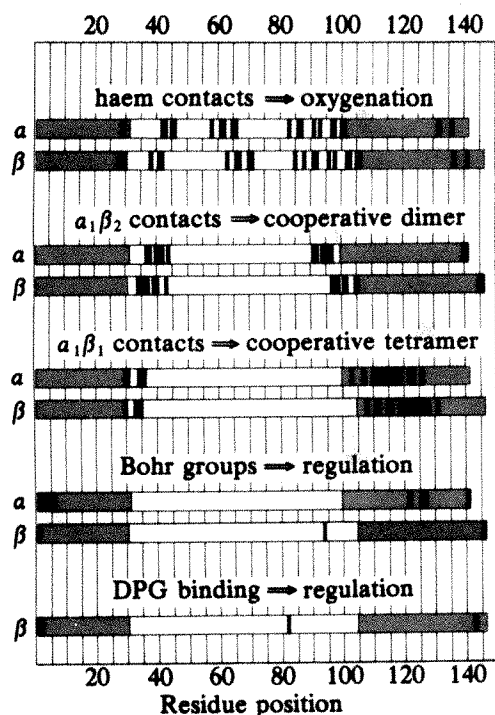

Fig. 2 Residues with well defined functional roles in human haemoglobin and the coding sequences of the mouse α and β globin genes. In the mouse α globin gene, the three coding sequences correspond to the amino acid residue positions 1–31, 32–99, and 100–141, (refs 22, 23) while in mouse β globin the sequences are 1–30, 31–104, and 105–146, which are structurally homologous to the α globin sequences^{24,25}.

strongly for or against this pathway in which the current first and third coding sequences arose from replacement of whole sequences in single steps. Goodman *et al.* have calculated that the number of nucleotide replacements per amino acid, from the point of gene duplication to the α and β chain amniote ancestors, was greater for the $\alpha_1\beta_2$ contact residues than for either the haem contact or $\alpha_1\beta_1$ contact residues¹⁵. In contrast, during the subsequent evolution to the current haemoglobins, the number of nucleotide replacements per position was greater for the $\alpha_1\beta_1$ contact residues than for either the haem or $\alpha_1\beta_2$ contact residues. If one takes the point of view that amino acid replacements signal the evolution of function at those positions, then these data support the idea that in the $\alpha_1\beta_2$ contacts evolved before the $\alpha_1\beta_1$ contacts.

The observation of a correlation between coding sequences and function presented here suggests that an investigation of the functional properties of the three polypeptide sequences of haemoglobin corresponding to the three coding sequences could provide new insight into gene-function relationships. Preparation of several of the sequences by digestion with trypsin is possible²⁸, since arginines are strategically located in both α and β chains, and in some haemoglobin variants^{18,19}.

I thank David R. Davies, James Hofrichter, William I. Wood, and Frank A. Ferrone for helpful discussions, and Walter Gilbert for arousing my interest in this problem.

Isolation of chromosomal origins of replication in yeast

David Beach, Melanie Piper & Sydney Shall

Biochemistry Laboratory, University of Sussex, Brighton, Sussex BN1 9QG, UK

Origins of replication have been identified in the DNA of viruses¹, mitochondria², bacterial plasmids³ and the bacterial chromosome⁴. However, origins of replication of eukaryote chromosomes have remained elusive because of the large size and sequence complexity of chromosomes and in particular for want of a suitable assay for their detection. Recent development of techniques for genetic transformation of yeast by autonomously replicating cytoplasmic plasmids^{5–8} now makes it possible to search for eukaryote origins in a manner analogous to that used for bacteria⁴. Here we describe the construction and properties of a plasmid which contains no effective eukaryote replication origin and whose efficiency of replication in yeast is greatly enhanced by insertion of certain fragments of yeast chromosomal DNA. We believe these to contain replication origins, since yeast transformants are shown to contain copies of the transforming plasmids.

The 13.7-kilobase recombinant plasmid pJDB248, consisting of the yeast 2 μ m plasmid, of pMB9 (a derivative of ColE1) and a 2.4 kilobase fragment of yeast DNA containing the *LEU2* gene, can be used to transform *Saccharomyces cerevisiae* M16, *leu2-3, his4-712^{FS}, ade2-1, lys2-1, SUF2*, to the *leu+* phenotype with a frequency of 10^4 – 10^5 transformants per μ g of DNA⁵. To obtain a plasmid whose presence in yeast can be detected, yet which lacks the origin of replication provided by the 2 μ m plasmid, a 1.5 kilobase *HaeII* fragment of pJDB248 containing the *LEU2* gene was recombined into the tetracycline resistance gene of the bacterial plasmid pBR325 (Fig. 1). The resultant 6.2-kilobase molecule, pDAM1, can transform a leucine-requiring strain of *Escherichia coli* (JA221) to *leu+* and to chloramphenicol resistance with equal efficiency.

However, the ability of pDAM1 to transform yeast (M16) to *leu+* is much impaired compared with pJDB248. pDAM1 gives rise to two clearly distinguishable types of yeast transformant (Table 1). One grows rapidly on leucine-free medium (1–10 transformants per μ g DNA) and probably results from recombination of pDAM1 or part of it with host chromosome¹⁰. The other is much more frequent (20,000 transformants per μ g DNA) but grows extremely slowly, the cells taking up to five days to form microcolonies visible to the naked eye. Cells from these colonies can be serially recombined on leucine-free medium, giving rise to further microcolonies, although the relative cloning efficiency is only 0.01–0.1% of that in the presence of leucine (Table 1). By contrast, pJDB248 transformants have a relative cloning efficiency of 78%. Furthermore, these pDAM1 transformants produce no visible turbidity after inoculation of a 2 ml leucine-free liquid culture even after a week. These data are taken to indicate that pDAM1 can survive and express the

LEU2 gene in yeast, but that the rate of growth of these transformants is limited by the very low copy number of the plasmid, perhaps no more than one molecule per 1,000–10,000 cells, resulting from the failure of pDAM1 to replicate.

It is possible to insert fragments of yeast DNA into pDAM1 and screen for those which give rise to yeast transformants which grow rapidly in the absence of leucine. Yeast whole cell DNA was digested with *Pst*I, ligated with the *Pst*I site within the ampicillin gene of pDAM1, and the total mixture cloned in *E. coli*. DNA preparations were made from 107 separate bacterial colonies and each was tested for its ability to transform yeast to *leu*⁺. Of such preparations 99 gave rise to microcolony transformants, indistinguishable in growth properties from those of pDAM1 itself, whereas 8 (pDAMY1 to 8) gave rise to colonies all of which grew rapidly, similarly to pJDB248 transformants (Table 1). Analysis by restriction digestion of these 8 DNA preparations showed two—pDAMY5 and pDAMY6—to contain the full length yeast 2 μ m plasmid which is endogenous to the strain (M16) from which the yeast DNA was prepared, and has one *Pst*I restriction site. The remaining 6 have *Pst*I inserts into pDAM1 ranging in size from 0.7 to 6.3 kilobases which are presumed to derive from the yeast chromosomal DNA (Table 1).

To determine whether copies of these plasmids are present in yeast transformants, lysates of single yeast colonies were prepared and the DNA analysed by agarose gel electrophoresis. The DNA was transferred to nitrocellulose filters and hybridised to ³²P-labelled pBR325 (Fig. 2). Tracks 1 and 2 of the autoradiograph contain DNA from the untransformed host strain (M16) and a low frequency transformant of pDAM1. Neither of these shows hybridisation to pBR325 detectable in this experiment. A high frequency transformant of pDAM1 was not tested as these colonies do not grow adequately on leucine-free media. However, transformants of pDAMY1, pDAMY2 and pJDB248 (tracks 3–8) have bands, hybridising to pBR325, with electrophoretic mobilities corresponding to the supercoiled (rapidly migrating) and open-circular (slower migrating) forms of the transforming plasmids. The presence of plasmids hybridising to pBR325 has been found in transformants of each of pDAMY1–8 (data not shown).

Why does insertion of certain fragments of yeast DNA into pDAM1 greatly increase the ability of transformants of this

Fig. 1 Illustration of the relationship between the plasmids pJDB248, pDAM1 and pDAMY1–8. pJDB248 consists of pMB9, the yeast 2 μ m plasmid and a 2.4-kilobase insert complementing the yeast *leu2* mutation. pDAM1 consists of pBR325 with a 1.5-kilobase insert containing the *LEU2* gene. This plasmid also carries chloramphenicol resistance (*Cm*^r) and ampicillin resistance (*Amp*^r). pDAMY1–8 are derived from pDAM1 by insertion of *Pst*I fragments of yeast DNA into the *Pst*I site (Δ) of the ampicillin gene of pDAM1. To construct pDAM1, pBR325 purified by the cleared lysate procedure⁹ and caesium chloride centrifugation was partially digested with the restriction endonuclease *Hae*II and ligated with a partial digest of pJDB248. The ligated DNA was used to transform *E. coli* JA221 *recA1*, *leuB6*, *trp* Δ *ES*, *hsdR*[–] *hsdM*⁺ *lacY* C600, to *leu*⁺ using minimal selective plates. pDAM1 was one such transformant, consisting of a 1.5-kilobase *Hae*II fragment containing the *LEU2* gene inserted into the tetracycline resistance gene of pBR325. Approximately 0.75 kilobases of this gene are absent. Yeast DNA was prepared from the strain M16 by lysis of protoplasts⁵, phenol extraction and ethanol precipitation. The DNA was digested with *Pst*I and ligated with a *Pst*I digest of pDAM1. This DNA was used to transform JA221 to chloramphenicol resistance and ampicillin sensitive colonies containing inserts of yeast DNA were subsequently selected.

plasmid to grow in the absence of leucine? It is most unlikely that this phenomenon is related to the efficiency of expression of the *LEU2* gene. This gene derived from yeast and carried in pDAM1 is expressed adequately in *E. coli*. Equally, it is unlikely that the result is a consequence of the ability of certain fragments of yeast DNA to allow vastly more efficient integration of pDAM1 into the yeast chromosome. Such integration may occur but it does not readily account for the presence of free plasmid copies in transformants. We believe that the poor growth of pDAM1 transformants is due to a very low copy

Table 1 Properties of pDAM1, its derivatives, and the yeast transformants which they produce

Plasmid	Size (kilobases)	Transformation frequency colonies per μ g DNA	Relative cloning efficiency <i>leu</i> [–] / <i>leu</i> ⁺ (%)
pDAM1	6.2 A	1–10	98
	B	20,000	0.01–0.1
pDAMY1	10.5	10,000	32
pDAMY2	11.2	10,000	50
pDAMY3	12.5	10,000	25
pDAMY4	9.1	10,000	65
pDAMY5	12.0	10,000	12
pDAMY6	12.0	10,000	8
pDAMY7	12.4	10,000	9
pDAMY8	6.9	10,000	2

The plasmids pDAMY1 to 8 are derived from pDAM1 as described in the legend to Fig. 1. Their size is given in kilobases and the approximate frequencies with which they transform the yeast strain M16 to *leu*⁺ are also given. The methods for yeast transformation was as previously described⁵. The relative cloning efficiency of yeast transformants was obtained as follows. Transformant colonies were spread on leucine-free minimal plates and allowed to grow overnight at 29 °C. Approximately 1,000 cells were suspended in 0.5 ml H₂O, aliquots of 100 μ l were spread onto leucine-containing and leucine-free minimal plates. Colonies were counted after 2 days except that pDAM1 microcolonies required 5 days to grow. The relative cloning efficiency is the ratio of the number of colonies on *leu*[–] plates to that on *leu*⁺ plates expressed as a percentage.

Fig. 2 Autoradiograph of ³²P-labelled pBR325 hybridised to undigested DNA of yeast transformants. Track 1: untransformed recipient strain M16. Track 2: rapidly growing transformant of pDAM1. Tracks 3,4: transformants of pDAMY1. Tracks 5,6: transformants of pDAMY2. Tracks 7,8: transformants of pJDB248. DNA was prepared from transformant colonies⁵, which had been grown on leucine-free media, and electrophoresed through 0.8% Agarose at 3 V cm^{–1} for 15 h. DNA was transferred to a nitrocellulose filter¹⁰ and hybridised with 4 \times 10⁶ d.p.m. ³²P-labelled pBR325 prepared by nick translation. The filter was exposed to Fuji Rx film with a Kodak intensifying screen at –60 °C for 4 days.

number of the molecule resulting from a lack of a eukaryotic origin of replication. The little replication that certainly does occur may be due to utilisation of the bacterial origin contained in pBR235. Those derivatives of pDAM1 which allow rapid growth of transformants are thought to be present in a higher copy number than pDAM1 because they contain origins of replication. This view allows an estimation of the frequency of origins in the yeast chromosome. Of 105 *Pst*I fragments of yeast DNA tested (excluding those two shown to be the 2 μ m plasmid), 6 contain origins. As the average size of the *Pst*I inserts in our clones is 2.3 kilobases there is, on average, one origin in every 40.2 kilobases of chromosome. This compares with the figures of 68 and 90 kilobases obtained respectively by electron

microscopy and fibre autoradiography of replicating yeast DNA^{12,13}. It remains to be established whether the apparent origins of replication detected in our system are indeed those utilised during normal chromosomal DNA replication.

Our work allows further isolation and subsequent sequence analysis of any desired number of yeast chromosomal replication origins. It is hoped that information about the nature of replication origins will aid studies of the biochemical mechanism of initiation of eukaryote DNA synthesis.

We thank David Sherratt for reviewing the manuscript and teaching us many of the techniques used in this work. The yeast strain M16 and bacterial strains JA221 and JDB248 were a kind gift from Jean Beggs. The work was supported by the MRC.

Is 3'-nucleotide rigid?

N. Pattabiraman, Shashidhar N. Rao & V. Sasisekharan

**Molecular Biophysics Unit, Indian Institute of Science,
Bangalore-560012, India**

Conformational analysis of nucleic acids and polynucleotides is far more complex than that of proteins and polypeptides, due to five single bond rotations in addition to the sugar puckerings in the monomer. Sundaralingam¹ proposed the concept of the 'rigid' nucleotides from analysis of crystal structure data, with the flexibility allowed only about the phosphodiester bonds. However, the crystal structure of deoxyguanosine-5'-phosphate^{2,3} indicates at *gt* conformation about the C-4'-C-5' bond against *gg* in a conformationally rigid nucleotide¹. Jack *et al.*⁴ considered the flexibility of nucleotides in tRNA about the C-4'-C-5' bond, thereby introducing the concept of 'non-rigid' ribonucleotides. Conformational flexibility of the furanose ring in DNA and RNA and their energetics using classical and quantum chemical methods have been reported⁵⁻⁸. We have examined the flexibility of 3'-nucleotides. α , the most important of the conformational parameters defining the 3'-end of a nucleotide unit⁹, has a value in the range 195°-270° in all the 3'-nucleotides, dinucleoside monophosphates and higher oligomers which have been surveyed. A survey of the proposed structures of polyribonucleotides^{10,11} also shows the values of α to be greater than 200°. However, the structures proposed for B-DNA by Arnott and Hukins^{12,13} and D-DNA by Arnott *et al.*¹⁴ have values of α of 155° and 141° respectively, much lower than the lowest observed value. The structure for B-DNA has two strong, short contacts (C-2' ... OP-1 = 2.64 Å and HC-2' ... OP-1 = 1.79 Å) which lead to an energetically unfavourable conformation. Hence, it is of interest to investigate whether, by allowing flexibility to the sugar moiety in the nucleotide unit, it is possible to make the structure energetically favourable. Here, conformational energy calculations were carried out to determine the range of α which would give rise to energetically favoured conformations with different sugar puckerings. Our analysis has shown that the theoretically obtained range is nearly the same as the preferred range in crystals, indicating the flexibility of the 3'-nucleotides.

Conformational energy calculations were carried out using classical potential functions¹⁵ for the sugar-phosphate fragment (Fig. 1a) of the nucleotide unit for both ribose and deoxyribose sugars. The sugar geometries were chosen from the minimum energy regions of the pseudo-rotation space^{7,8}. For each of the

values of Φ (defined in Fig. 1b legend), energy was minimised for each value α over a few geometries. Φ was varied from 0° onwards at intervals of 18° , and α from 120° to 300° at intervals of 10° and 1° (in the minimum energy region). Outside the specified range for α , for all geometries considered, strong short contacts were observed between the atoms in the phosphate group and the groups of atoms attached at the C-5' and C-2' atoms. The torsion angles β and ϵ were fixed respectively at their average values of 290° and 50° (ref. 16). The other two pendant oxygens were fixed tetrahedrally. Energies were also obtained for *gt* and *tg* conformations about the C-4'–C-5' bond. The general features of the Φ – α plot do not change for small changes from the average values of β and ϵ . However, for the *tg* conformation, it was observed that the C-3' *endo* region does not have energetically favourable conformations for both deoxyribose- and ribose-phosphate fragments. Details of this will be published elsewhere.

Figure 2 shows the energy contours at an interval of 1 kcal mol⁻¹ from the minimum in the Φ - α space for the ribose-phosphate fragment. Observed values for α in many crystal structures are also plotted. The plot shows the global minimum

Fig. 1 *a*, The ribose-phosphate fragment of a ribonucleotide. *b*, Definition of the pseudo-rotation phase parameter in the pseudo-rotation space.

at $\alpha = 280^\circ$ in the C-2' *endo* region. The minimum has been indicated by a vertical line, as, along this line energy does not vary significantly. The energy varies differently in two directions about the minimum. On the left ($\alpha < 280^\circ$), the energy rises very gradually as α decreases. On the right ($\alpha > 280^\circ$), as α increases, the energy increases very rapidly due to strong unfavourable non-bonded interactions between atoms in the phosphate group and hydroxyl group and hydrogen atoms at C-5'. Apart from the global minimum at $\alpha = 280^\circ$ in the C-2' *endo* region, the plot also shows two local minima in the C-3' *endo* region at $\alpha \approx 200^\circ$ and $\alpha \approx 270^\circ$. Note also that transitions are possible from the C-3' *endo* to C-2' *endo* regions via the O-1' *exo* region at high values of α by crossing an energy barrier of 1 kcal mol⁻¹.

Figure 3 shows a similar plot for the deoxyribose-phosphate fragment. As in ribose, there is a global minimum in the C-2' *endo* region at $\alpha = 280^\circ$ (indicated by a vertical line for reasons stated above). Also as in ribose and for reasons already stated, this plot indicates a rapid rise of energy as α is increased to the right of the global minimum. To the left ($\alpha < 280^\circ$) there is a gradual rise in the energy. However, unlike in ribose, there is another local minimum around $\alpha \approx 190^\circ$ in the C-2' *endo* region in addition to two local minima in the C-3' *endo* region (at $\alpha \approx 180^\circ$ and $\approx 270^\circ$). The plot also shows that conformational transitions between the C-3' *endo* and C-2' *endo* regions are possible via both O-1' *exo* and O-1' *endo* regions. At low values of α ($\approx 200^\circ$) the barrier to transition via either O-1' *exo* or O-1' *endo* is 2 kcal mol⁻¹. At high values of α ($\approx 270^\circ$) the barrier via O-1' *exo* is 1 kcal mol⁻¹ and is very high via O-1' *endo*.

A comparison of the Φ - α plots for ribose- and deoxyribose-phosphate fragments shows a larger conformational flexibility in the case of the latter. At low α values ($\approx 180^\circ$), C-2' *endo* region is prohibited for ribose because of strong short contacts between the bulky OH group at C-2' of the sugar and the atoms in the phosphate group. These are relieved to some extent in deoxyribose, where only hydrogen is attached at C-2'. This explains the occurrence of a local minimum at $\alpha \approx 190^\circ$ in the C-2' *endo* region. However, for both the sugars, we noted that in both the C-3' *endo* and C-3' *exo* regions, very low values of α , such as 140° - 150° , are prohibited. Energy contours as high as 4-5 kcal mol⁻¹ pass through the regions at such low α values. In the C-3' *endo* region the local minimum at $\alpha \approx 200^\circ$ in the case of ribose shifts by about 20° on the lower side in the case of deoxyribose; this is due to the presence of hydrogen at C-2' instead of a bulky hydroxyl group. The comparison also reveals that transitions between C-3' *endo* and C-2' *endo* regions are very restricted in ribose, but are relatively easy in deoxyribose. Whereas in ribose only high α transitions are possible via the O-1' *exo* region, both low and high transitions via the O-1' *exo* and O-1' *endo* regions are possible for deoxyribose.

Fig. 2 Φ - α plot for the ribose-phosphate fragment. Energy contours of 1.5 kcal mol⁻¹ in the C-3' *endo* region are shown. \blacktriangle Denotes 3'-nucleotides, \blacksquare denotes dinucleoside monophosphates and higher oligomers, \odot denotes proposed structures of polynucleotides. \odot^b , RNA-11 (ref. 11); \odot^a , A-RNA (ref. 10).

Fig. 3 Φ - α plot for the deoxyribose-phosphate fragment. \blacktriangle Denotes 3'-nucleotides, \blacksquare denotes dinucleoside monophosphates and higher oligomers, \odot denotes proposed structures for polynucleotides. \odot^a , C-DNA¹⁸; \odot^b , A-DNA¹⁷; \odot^c , B-DNA^{12,13}; \odot^d , D-DNA¹⁴.

It is found that for compounds containing ribose sugars, values of α mostly range between 200° and 240° in the C-3' *endo* region and between 220° and 270° in the C-2' *endo* region. Two of the proposed structures for polynucleotides (A-RNA and RNA-11)^{10,11} also lie in the C-3' *endo* region. In the case of deoxyribose sugar compounds, the observed points are spread over a wider range of α than in ribose in both C-3' *endo* and C-2' *endo* regions. It is found from the plots that energetically favourable conformations are possible with $\alpha > 180^\circ$, and that for structures with $\alpha < 150^\circ$ unfavourable conformations result. The refined model of B-DNA¹³ ($\alpha = 155^\circ$) lies on the 3 kcal mol⁻¹ contour in the C-3' *exo* region of the Φ - α plot for the deoxyribose-phosphate fragment. However, β and ϵ in the refined structure of B-DNA are different from those used in the present calculations. Conformational energy calculations carried out using the conformational parameters of the refined model reveal that the model is 4 kcal mol⁻¹ above the minimum and thus energetically unfavourable. Further, V.S. has pointed out that the structure is 2 kcal mol⁻¹ above the minimum in the Φ - χ plot⁷, which emphasised the influence of the sugar geometry on the value of χ , the glycosidic torsion angle. Considering the nucleotide unit as a whole, the refined model of B-DNA¹³ is more than 5 kcal mol⁻¹ above the minimum despite allowance for the flexibility of the sugar unit.

We have used these results to produce a refined model for B-DNA which differs from that of Arnott and Hukins¹³. We have refined a right-handed double-helical model which is in good agreement with the X-ray diffraction data and has an energetically favourable conformation. We also find that the left-handed double-helical model for B-DNA is energetically favourable and is in good agreement with the X-ray diffraction data. The details of the two structures are published elsewhere.

Electron density map of chicken heart cytosol aspartate transaminase at 3.5 Å resolution

V. V. Borisov, S. N. Borisova, N. I. Sosfenov & B. K. Vainshtein

Institute of Crystallography, Academy of Sciences, Moscow 117333, USSR

Aspartate transaminase (EC 2.6.1.1., Asp-transaminase) has been studied extensively, and much is now known about its physico-chemical, catalytic and other properties¹. X-ray studies that can provide a structural foundation for the events that occur during the transamination reaction are under way on three species of Asp-transaminase: the cytosolic enzyme from pig² and chicken³ hearts, and the mitochondrial chicken heart enzyme⁴. We describe here the interpretation of an electron density map of Asp-transaminase from chicken heart cytosol at 3.5 Å.

Aspartate transaminase catalyses the reaction

The enzyme is dimeric (molecular weight 93,000), consisting of two chemically identical subunits. Crystals were grown in the presence of α -methyl aspartate (α -Me-Asp) as previously described³. Their space group is $P2_12_12_1$, with cell dimensions $a = 62.7$ Å, $b = 118.1$ Å and $c = 124.5$ Å, and they contain one dimer in the asymmetric unit⁵. The 3.5 Å resolution map was calculated using phases obtained from three isomorphous derivatives, improved by making use of the non-crystallographic symmetry relating the two subunits in the molecule⁶. Other states of the enzyme were obtained by soaking experiments, and examined at lower resolution using difference maps.

Tracing the polypeptide chain was facilitated by the extensive secondary structure present in each subunit. Nine α -helices were located, including one 48 Å long, and a number of β -strands, five of which form a parallel β -sheet in the core of the subunit. Figure 1 shows part of the electron density map including the long helix and part of core β -sheet. It was possible to interpret the electron density map in terms of a unique chain tracing, a schematic drawing of which is shown in Fig. 2. According to the current classification of globular proteins⁷, Asp-transaminase is an α/β protein. Figure 2 shows that the subunit is composed of three parts of about equal size, defined by the preferential directions of the α -helices and β -strands. The three directions are almost mutually perpendicular. Of these three parts, only one, shown in the lower centre of Fig. 2, can be considered as a separate domain, the others are combinations of fragments from the N and C termini. The separate domain shows a close resemblance to the well-known 'nucleotide binding domain', first discovered in the NAD-dependent dehydrogenases^{8–11}, and then found in a number of other enzymes including phosphoglycerate kinase¹², phosphoglycerate mutase¹³, rhodanese¹⁴ and glycogen phosphorylase^{15,16}. In Asp-transaminase this domain is composed of five parallel β -strands alternating with five antiparallel helices. Figure 3 shows a drawing of this domain in comparison with the NAD-binding domain of lactate dehydrogenase^{17,18}. Interestingly, both pyridoxal phosphate-containing enzymes studied by X-ray analysis (Asp-transaminase and glycogen phosphorylase) have such a domain in their structure; other pyridoxal enzymes may also contain domains of this kind.

The enzyme's active site was first located from a difference map of the apoenzyme at 5 Å resolution³. At 3.5 Å resolution it can be concluded that the negative density seen in the difference map between the native and apoenzyme corresponds only to the pyridine moiety of the coenzyme; the phosphate moiety is probably replaced by a dianion from the solvent in the apoenzyme crystals. The phosphate group of the coenzyme has been recognised in the 3.5 Å native map as the highest density peak located close to the previously identified pyridine ring. The coenzyme is located at the carboxy end of the β -sheet of the nucleotide-binding unit, with its phosphate group at the N terminus of the first upper helix as shown in Fig. 2, suggesting an interaction of the charged phosphate with the helix dipole¹⁴. The coenzyme is located about 7 Å from the subunit interface, represented by the upper face of the drawing in Fig. 2. The substrate binding region, deduced from a series of difference maps (see below) is placed between the coenzyme and chain segments from the N and C termini (see Fig. 2). Overall the active site is located at the interface of the three parts of the subunit noted above.

Spectroscopic studies on crystals of pig cytosolic enzyme¹⁹ suggested that the complex with α -Me-Asp is a mixture of two spectroscopically discernable forms, probably representing differences in the coenzyme orientation. However, in the X-ray studies the electron density for α -Me-Asp can be accounted for by a single conformation and a fixed geometry of the substrate analogue in both forms can be assumed. The density of the pyridine ring is slightly less pronounced but the span of possible orientations is only 15–20°. We have shown previously³ that these crystals of Asp-transaminase are catalytically competent, allowing us to examine different states of the enzyme. Previous studies³ have shown that crystals washed free of α -Me-Asp, and colourless crystals of the pyridoxamine form of the enzyme gave 5 Å resolution difference maps containing similar features interpreted as conformational changes in the enzyme. Now it can be seen that these changes are located in a wide region including the substrate-binding area and the C-terminal helix. It seemed possible that the conformational pattern in this area is determined by the presence of substrate carboxyl groups. To check this the complexes with erythro- β -hydroxyaspartate, maleate and succinate have been studied.

Crystals were soaked in a stabilising solution³ (without α -Me-Asp) with the addition of one of the three mentioned

Fig. 1 Superposition of the eight sections of the electron density map of Asp-transaminase from chicken heart cytosol (at 3.5 Å resolution). The sections are perpendicular to the z axis, with the distance of 0.8 Å between neighbouring sections. A big helix 48 Å long is seen at left side. The horizontal β -strands of a parallel β -sheet in the centre are a part of the 'nucleotide-binding domain'.

Fig. 2 Schematic drawing of the model of Asp-transaminase subunit built from secondary structure elements. α -Helices are shown as cylinders and β -strands as arrows, those belonging to the 'nucleotide-binding domain' shown as space-filled arrows. The coenzyme is shown covalently linked to α -Me-Asp.

compounds, at 50 mM concentration. Crystals soaked with erythro- β -hydroxyaspartate acquired a gingerish colour after 1 hour, which could be maintained for several months. The X-ray experiments were performed on crystals soaked for 2 h. Crystals soaked with maleate or succinate became a distinctly brighter yellow than the original α -Me-Asp complex. X-ray experiments were done after 1–2 days of soaking. At 5 Å resolution, the difference maps of all three complexes contained some features in the substrate-binding area but no conformational changes. A similar X-ray experiment on the abortive complex of the pyridoxal form of the enzyme with 2-oxoglutarate gave a difference map showing conformational changes localised in the same region as the substrate-free form of the holoenzyme³, but of opposite sign.

It is of interest that the conformations of the apoenzyme and the α -Me-Asp complex are similar. A number of prominent positive peaks observed near more extended features interpreted as conformational changes, suggest that some of the conformational changes can be ascribed to the interaction of ions. After the removal of α -Me-Asp one such positive peak persists near a position previously occupied by the distal carboxyl. Another is seen in the vicinity of the C-terminal helix. It can be supposed that an anion replacing the substrate carboxyls is a cause of the conformational changes in the substrate-binding area. Also, in relation to the apoenzyme, the absence of negative density for the removed phosphate of the pyridoxal phosphate or substrate analogue may be explained by similar anion replacements. It is possible that the additional space created by removal of the coenzyme allows the anion to bind without causing conformational distortions to the adjacent protein framework.

In the study of Asp-transaminase much attention has been paid to the so-called syncatalytic phenomena observed after the addition of pairs of substrates (such as the L-glutamate/2-

oxoglutarate pair)^{20–24}. These effects have been treated in terms of conformational changes concomitant with the formation of covalent intermediates in the course of the catalytic process. It is tempting to assume that the conformational changes discussed here are a part of the same picture. However some remarks seem to be relevant: (1) The conformational changes observed by us are concomitant not with catalysis but with binding of substrates or inhibitors. (2) The conformational changes that accompany the transition between substrate-binding, and substrate-free forms are different in two subunits, this asymmetry may be explained by restrictions imposed by crystal packing. (3) The possibility that the observed changes are a property only of the chicken heart cytosol enzyme cannot be excluded. (4) In addition to the gross conformational changes observed at 5 Å resolution, more subtle changes are probably also present which may be of the most important functional meaning. It may be predicted that comparative X-ray studies of different states of Asp-transaminase at higher resolution should soon clarify many of the problems discussed here.

We thank Yu. V. Nekrasov, A. A. Vagin and V. M. Kochkina for valuable assistance, and L. N. Johnson for the picture of 'nucleotide-binding domain' in phosphorylase *b*. We also thank Professor A. E. Braunstein for valuable advice and discussions. *Note added in proof:* Recently similar three-dimensional structure and conformational changes have been described for chicken mitochondrial Asp-transaminase²⁵.

MATTERS ARISING

Information transmission in remote viewing experiments

IN a recent letter to *Nature*¹ Marks and Kammann offer criticism of the SRI experiments in 'remote viewing', the ability of certain individuals to access and describe, by means of mental processes, information blocked from ordinary perception by distance or shielding^{2,4}. They hypothesise that the apparent success in these experiments may simply be an artefact of statements in the subjects' transcripts which provide extraneous cues useful to judges attempting to blind match transcripts to target sites. They then argue that examples from the transcripts of the first published experiment—a nine-trial series with subject Price²—support their hypothesis. We present here experimental evidence that demonstrates that this conjecture is false.

On reading Marks and Kammann, one of us (C.T.T.), who had no connection with the original Price series, offered to independently reanalyse that series to test the validity of the Marks–Kammann hypothesis. He edited the transcripts carefully, removing all phrases suggested as potential cues by Marks and Kammann, and removing any additional phrases for which even the most remote *post hoc* cue argument could be made. The series was then rejudged by a new independent qualified judge (having previously shown competence in blind matching and verbal content analysis of similar materials) who was unfamiliar with the Price series. The materials turned over to the judge consisted of the newly edited transcripts presented in random order, and the list of target sites, also in random order (different from both the transcript random order and from the order of original target usage). The judge was instructed to provide, on a blind basis, a set of target/transcript correspondence ratings, which required that she visit each target site and rate transcripts to targets on a scale of 0–100 for all possible combinations, generating a 9×9 matrix. These data also yield the conventional overall measure of target/transcript correlations by indicating each first place match from the set of nine for each target.

The result of the blind matching of transcripts to target sites in the rejudging was that seven of the nine were again correctly matched. The appropriate statistic for this overall matching result is derived assuming non-independent assignment of transcripts to target sites (as in guessing the order of a random sequence of the digits one through nine, each used once)⁵; the result (seven out of nine correctly matched) is significant at

$P < 10^{-4}$. Furthermore, the more detailed target/transcript rating matrix was analysed by an exact factorial method⁶; the result obtained by this analysis was significant at $P = 2.2 \times 10^{-5}$. The greater significance obtained by the latter, more sensitive measure of target/transcript correlations reflected the following important fact: the judge found that, with the exception of two transcripts that did not seem to correspond to any site, the remaining seven transcripts each showed high correlation to one (correct) site and low correlation to the others. This is in direct contradiction to the implication of Marks and Kammann that little target/transcript correlation existed, and that matching is possible only on the basis of artefactual cues.

Therefore, on the basis of an independently conducted empirical test, we reject as invalid the Marks–Kammann conjecture that success in the first-published study on remote viewing is to be attributed to cueing artefacts rather than to transcript/target correlations. It is also important to note that the Marks–Kammann critique did not address the quality of the remote-viewing descriptions in the transcripts *per se*, but was instead limited to criticism of a particular judging procedure used to evaluate those descriptions. With regard to the descriptions themselves, we note that in the nine-transcript series in question, when the target was a boat marina the subject gave a consistent narrative that began with "What I'm looking at is a little boat jetty or boat dock along the bay. It is in a direction about like that (pointing) from here. Yeah, I see the little boats, some motor launch (sic), some little sailing ships. . . ." For a landmark Hoover Tower site, the subject summarised his impressions as "The area—I have a place—seems like it would be Hoover Tower". For a recreational swimming pool site with a $75 \text{ ft} \times 100 \text{ ft}$ rectangular pool and a 110 ft diameter circular pool, the subject made a drawing of the target area as centred about two pools of water, which he dimensioned as a $60 \text{ ft} \times 89 \text{ ft}$ rectangular pool and a 120 ft diameter circular pool; and so forth. Furthermore, as pointed out above, blind content analysis of the transcripts, which provides a sensitive measure of the degree of target/transcript correspondences, confirms objectively the subjective impression of above-chance correspondence that one infers from examples such as the above. With data of this quality we would argue that it is not surprising that empirical test failed to confirm the cueing-artefact hypothesis put forward by Marks and Kammann, but rather confirmed that the target/transcript matches in the first remote-viewing

study are to be attributed (as originally interpreted) to the quality of the subject's descriptions themselves.

Furthermore, in the extensive SRI replication studies³, which also yielded significant results, the Marks–Kammann criticisms do not apply in principle. Target lists and transcripts were separately randomised, and transcripts were carefully checked before judging to ensure absence of any phrasing for which even a weak *post hoc* potential-cue argument could be made.

Given (1) the failure (by empirical test) of the cueing-artefact hypothesis to account for the success of the first-published SRI remote-viewing study², (2) the inapplicability of this hypothesis to the later SRI replication studies³, and (3) the replication of this work in our own and other laboratories, the bulk of which is successful⁷, the data continue to confirm the original conclusion that remote viewing is a viable human perceptual capability.

Is Cassiopeia A a black hole?

SHKLOVSKY has recently¹ summarised evidence in favour of a black hole in Cas A in contrast to my arguments^{2,3} in favour of a binary neutron star. I defend my view here.

The fact that Cas A has not been reported as a supernova is disturbing as it has an assumed interstellar absorption A_v of 4.3 mag, and a distance of 2.8 kpc. On the other hand, Tammann⁴ has suggested a mean supernova rate of some $10^{-1.1 \pm 0.3} \text{ yr}^{-1}$ for our Galaxy; a similarly high rate is needed to account for the observed neutron stars, both pulsars and transient X-ray sources. These estimates may be reconciled if supernovae are sometimes obscured, by an adjacent dense hydrogen cloud, say, whose absorptivity is

temporarily raised by ionisation. Note that such an explanation would similarly be able to explain the inclination dependence⁴ of supernova rates in external galaxies, and the absence so far of Type 2 explosions in irregular galaxies.

Cas A is anomalously bright at radio frequencies, and one is tempted to conclude that it has an anomalous mass. From optical observations, one infers a mass $<1 M_{\odot}$. If this mass is concentrated in a network of filaments, of electron density $>10^3 \text{ cm}^{-3}$, then the X-ray luminosity can similarly stem from a mass $<1 M_{\odot}$. (McKee's assumption of homogeneous shells need³ not be realistic.) And if the velocity field of the quasi-stationary flocculi reveals³ a peculiar velocity of $(165 \pm 15) \text{ km s}^{-1}$ of the whole remnant, towards north-northeast and towards us, then the supernova remnant must be lighter than its recoil partner (unless the latter moved even faster), again supporting a mass $\leq 1 M_{\odot}$ in the conservative case.

This recoil partner cannot be very luminous because it has not even been detected. Very careful searches have been performed near the divergence centre of the optical knots, whereas the recoil may have removed it southwards. I think that a low mass binary containing a neutron star is a likely candidate. The neutron star's surface temperature⁵ may be anything between 10^5 K and 10^7 K , depending on pion condensation in its interior. Its relativistic wind may be shielded by a cocoon formed from the wind material of its companion. And it can be the source of the cosmic rays in the nebula, and of the soft radio flare⁶ which has probably occurred between 1967 and 1974. Alternatively, the recoil partner may be a second binary pulsar⁷.

Evidence for late Precambrian plate tectonics in West Africa

BLACK ET AL.¹ have reported further evidence for plate tectonics in the Precambrian based on their study of a 600-Myr-old collision zone proposed^{2,3} along the eastern margin of the West African craton. In places, this margin is associated with a negative-positive gravity anomaly pair⁴. A case for plate tectonics in the Canadian Shield, following the initial suggestion⁵ and a description of the geological evidence⁶, has centred around interpretation of similar anomalies

present at several structural boundaries proposed as collisional suture zones⁷⁻¹⁰. The type structure derived from the anomalies comprises an older crustal block, that thickens towards the suture, in steep contact with a thicker and denser, younger crustal block, both blocks being in approximate isostatic equilibrium¹¹. A similar model has been proposed^{12,13} for the eastern margin of the West African craton. These gravity models (Canadian and West African) are comparable with a 'basement reactivation' model proposed for collided continents¹⁴.

We include the West African anomalies in a growing family of anomalies that seem to be collision-related phenomena reflecting a particular crustal configuration developed at suture zones. The gravity anomalies in the Canadian Shield occur along 1,800 and 1,000 Myr old orogenic belts. The addition of a 600 Myr old example from Africa suggests a continuum throughout most of Proterozoic time (1,800–600 Myr BP). Another example of paired anomalies, currently under study, along the southern Appalachians apparently extends the continuum into the Phanerozoic to ~450 Myr BP. Similar gravity signatures have been described from the Precambrian shields of Australia¹⁵ and India¹⁶. Precambrian collisions proposed in Europe and South America¹⁷ may provide more examples.

BLACK ET AL. REPLY—We agree with Thomas et al. on the importance and significance of paired gravity anomalies

along collisional suture zones, although we feel that detailed seismic information is required to perfect the model.

Note, however, that the anomalies along the eastern edge of the West African craton fall into two categories: (1) anomalies of long wavelength for which one can envisage a crustal structure similar to that proposed by Thomas et al. to explain coupled negative and positive anomalies along a cryptic suture. In Togo–Benin, however, in assessing the negative anomaly, one has to take into account the sediments of the passive continental margin (Buem, Atacorian). (2) Positive anomalies of shorter wavelength corresponding to more superficial unrooted structures and displaying subvertical to easterly dipping geometry in accord with the general movement pattern with thrusting towards the craton. Field observations show that these anomalies are due to basic and ultrabasic bodies emplaced along the suture^{1,2}.

The location of the two types of anomalies seems to be related to the geometry of the craton, which we believe reflects the original shape of the continent before collision. The first type of paired gravity anomalies occurs in Togo–Benin where the craton forms a promontory and where collision is thought to have been most intense. This situation led to the complete disappearance by subduction of the oceanic floor and of the active margin to the eastern continent, thus bringing into direct contact by underthrusting the low-grade metasediments belonging to the passive continental margin of the craton, and high-grade basement of the eastern continent. In contrast, the second type of anomalies are located in an embayment where island arc and cordilleran volcanoclastic assemblages of the active margin to the eastern continent have been preserved.

The Bouguer anomaly map of Canada suggests that several paired gravity anomalies are arcuate in form and occur along promontories, such as the Thelon front between the Slave and Churchill provinces³.

We believe at present that the stress and deformation pattern together with the gravity signature have largely been controlled by the geometry of the colliding passive continental margin^{4,5}.

ELECTROPHORESIS

The official journal of the newly founded
Electrophoresis Society

Electrophoresis is one of the most important methods for the investigation of biological materials and probably the most efficient procedure for the analysis of proteins and other charged species.

Despite the wide-spread use and the rapid development of electrophoretic methods there was, so far, no journal in existence that was entirely devoted to this field.

Electrophoresis is designed to close this gap. It will provide a unique forum for the publication of contributions that were, in the past, scattered throughout different journals and very often escaped the attention of those engaged in the development and use of electrophoretic methods.

Research reports will be described with particular emphasis on advanced methods of electrophoresis. Topics will include new and improved analytical and preparative methods and theoretical aspects.

Electrophoresis will stimulate communication between scientists in many fields such as biochemistry, clinical chemistry, genetics, immunology, microbiology and food science by presenting innovative applications of electrophoretic methods.

Subscription details

1980. Volume 1. Published bimonthly. Annual subscription rate DM 176,- plus postage and handling fee. A special subscription rate of DM 112,- is available for members of the "Electrophoresis Society" and the "Japanese Society of Electrophoresis". Members must send their orders directly to the appropriate association. (orders for the U.S.A. and Canada will be invoiced in US \$)

Electrophoresis publishes articles predominantly in English, but also accepts contributions in German and French. The highest editorial standards are obtained through the cooperation of an Editorial Board, composed of world-renowned specialists, assuring the reader that each and every article will demonstrate a new concept of approach.

Electrophoresis publishes original papers, short communications and review articles. Other features will include book reviews, important conference dates and miscellaneous information.

Editor-in-Chief Prof. B. J. Radola, Lehrstuhl für Chemisch-Technische Analyse und Chemische Lebensmitteltechnologie, 8050 Freising-Weihenstephan, West Germany

Associate Editor Prof. R. C. Allen, Dept. of Laboratory Animal Medicine, Medical University of South Carolina, Charleston, U.S.A.

BOOK REVIEWS

Essay-writing is difficult

Eric Ashby

"THE essayist," wrote E. B. White, himself a virtuoso in essay-writing, is "sustained by the childish belief that everything he thinks about, everything that happens to him, is of general interest." Essays can be classified as those written to instruct, to persuade, or to entertain. If they have to be limited in length to some 1,200 words, preferably about some scientific topic, they are a difficult art-form for any of these three purposes. This is what Professor Morowitz attempts in this book. It is an assemblage of 57 titbits from the magazine *Hospital Practice*: some to instruct, some to persuade, and all — the author himself confesses — intended to entertain.

To be fair to these essays it is essential to remember that they appeared one at a time, as appetisers, in a magazine devoted (to judge from its title) to the sober topic of how to care for the sick. To offer the reader 57 appetisers, all at once, undiluted by articles on pre-natal clinics and intensive care units, is to expose the appetisers to unreasonable criticism. Only a master in essay-writing could hope to stand up to such criticism. The blurb on the dust-cover "invites comparison to *Lives of a Cell* by Lewis Thomas." This is not fair, for pleasant as some of Morowitz's whimsical pieces are, he is not in the same league as Lewis Thomas, for reasons I shall try to summarise at the end of this review.

Here is a sample of the more enjoyable essays. Morowitz receives a birthday card with the caption: "According to biochemists the materials that make up the human body are only worth 97 cents." He goes through the catalogue of a biochemical company and finds that the market price of the compounds in his body, synthesised from the 97 cents-worth of elements, is of the order of 6 million dollars: a nice reminder that "information is much more expensive than matter." The bicentennial of the United States in 1976 moves him to reflect that 1976 is also the centennial of "the second most significant document produced in the United States, Josiah Willard Gibbs' paper *On the Equilibrium of Heterogeneous Substances*: and there follows an epitome of Gibbs' contribution to science. In another essay he describes a conference of

The Wine of Life, and Other Essays on Societies, Energy and Living Things. By H. J. Morowitz. Pp.265. (St Martin's Press: New York, 1979.) \$10.

ecologists at the Hague and is shocked at the way they fouled the air with cigars distributed at a reception in their honour. This was an unfortunate theme to choose, for it does invite comparison with Thomas' essay on a medical conference at Atlantic City (*On Societies as Organisms*). Lewis flutters like a graceful bird over the scene of the conference; Morowitz (it seems to me) wades through the scene in gumboots. The essayist (if he has the skill) can be Mozartian in 1,200 words; he cannot, in 1,200 words, be Wagnerian.

Occasionally Morowitz does bring it off. He picks on a phrase in a report about experiments on animals: "the animals were sacrificed." This, in Britain, could mean simply that the worker was complying with the requirements of the Cruelty to Animals Act of 1876. But think (writes Morowitz) about the meaning of the word 'sacrifice': "the slaughter of an animal as an offering to God or a deity." He draws a parallel between the practice of animal sacrifice in religions, which is being phased out, and animal sacrifice in the cause of science, which is on the increase: the incinerator replacing the burnt offering, the control group of rats replacing the Old Testament goat which was not slaughtered; the purpose, however, remaining the same: to "ward off disease, illness, and old age . . .". This is excellent satire, and timely for British readers, for there are at present two Bills before Parliament for the reform of the Cruelty to Animals Act of 1876.

The purpose of some of the essays is to debunk, and Morowitz does this well, if a little heavy-handedly. He publishes a nice letter he wrote to his hairdresser, who tried to persuade him to have his hair treated with a conditioner containing nucleic acid (at, presumably, exorbitant cost). So he considers just what effect applications of DNA or RNA might have on the scalp, and he ends by advising his hairdresser to beware of being an agent for the abuse of words like nucleic acid, proteins, lecithins,

and other mumbo-jumbo borrowed from science to promote profits in the cosmetic industry.

One more example: the essay from which Morowitz chose the title for his book. It is as neat an account as one could get into four pages of the way Claude Bernard (whose home was in the Beaujolais region of France) and, after him, Pasteur, were inspired to do some of their best work by considering "how grape juice becomes wine". This is the use of the essay to instruct and it is as instructor that Morowitz is at his best. He is undoubtedly well read, scholarly, and — consistent with E. B. White's prescription — he wants to tell you what has interested him since the last issue of *Hospital Practice*.

Why, then, do I have reservations (not shared by reviewers quoted on the dust-cover) about the quality of these essays? I have two reasons. One is that essays, unlike articles, published lectures, and monographs, have to be judged primarily upon felicity of style. A good essay sparkles with surprises; it captures your attention without being importunate; it can (Dr Johnson said this about essays) be "an irregular, undigested piece" but it has to convey delight, like a kitten playing with a ball of wool. To do this at all is difficult; to do it on a scientific theme is extremely difficult. I don't find Morowitz's style felicitous: a subjective judgement, of course, and maybe it's my fault and not his.

Second, the essay, unlike other kinds of writing, should tell you a lot about the essayist. After reading Montaigne, Lamb, Jorge Borges — and in science T. H. Huxley, J. B. S. Haldane, and Lewis Thomas — you feel you know the essayist: his prejudices, his enthusiasms, what he stands for. The relation between reader and writer has some of the qualities of friendship. Irregular and undigested as essays may be, they add up to the portrait of a distinct personality. This is what I missed in *The Wine of Life*. □

British stratigraphy

F. Wolverson Cope

A Dynamic Stratigraphy of the British Isles. By R. Anderson, P.H. Bridges, M.R. Leeder and B.W. Sellwood. Pp.301. (George Allen and Unwin: Hemel Hempstead, UK, 1979.) Hardback £15; paperback £7.95.

APTLY titled, this book describes the evolution, over a period of about 3,000 million years, of that part of the Earth's crust occupied by the British Isles.

The past two decades have seen a revolution in geological thinking. Major factors in this have been the increasing capability to date rocks radiometrically, the study of palaeomagnetism, remarkable advances in sedimentological interpretation based upon increased knowledge of modern sedimentary processes, the exploration of sea and ocean beds and of the crust beneath them, and the theory of plate tectonics which has arisen from these. This is an appropriate time for some stocktaking.

The authors are to be congratulated on having so successfully re-interpreted, indeed in some cases interpreted for the first time in a meaningful way, the many phases in the history of the British Isles area. They have explained the evolution of this part of the Earth's crust in the light of plate tectonics, and have added considerably to the story by using results of hydrocarbon exploration in the North Sea.

With a necessarily chronological

treatment, the reader will gain a broad appreciation of the stratigraphy of the British Isles and the surrounding seas. The book highlights the value of sedimentological studies in stratigraphy. Fossils are used almost exclusively as ecological indicators; the results of their use in correlation are taken very much as read so that some stratigraphical problems are glossed over.

The account is well written. It is profusely illustrated with carefully executed maps and diagrams, and the volume is pleasant and easy to use. Though not advocating expansion in technical vocabulary, one feels that a tautological expression such as "facing confrontation" (page 165) should be eliminated. On the other hand, technical terms which come so readily to hand are sometimes better avoided as in "Perhaps palaeoslopes were directed southwards in this area" (page 234) when speaking of slopes.

This book should be invaluable to students and others who wish to gain some understanding of the evolution of the Earth's crust in the British Isles area. It should serve many generations as a useful framework of spatial and dynamic relationships without which stratigraphy must fail to inspire.

Adopting a metaphor suggested by non-use of the adjective *seminarial* (in the gloss on the back of the book), one would say that the four authors have combined most successfully in the production of a lively 'zygote', especially as it might never have come about but for "... a seminal [sic] encounter"! □

Chinese revelation

M. Christine King

China's Road to Development. Edited by Neville Maxwell. Pp.365. (Pergamon International Library: Oxford, 1979.) Hardback £21; paperback £5.25.

It is a strange fact of life that those most responsible for making history have always been the least able to record it for posterity. The result of this is that, from time to time, history has to be re-written. The present volume on China, an enlarged edition of a collection of essays first published in 1976, is perhaps an apposite example of this phenomenon. It appears at a time when China is deliberately revealing its own past in order to point a way to the future. Thus many of the 'development' theories outlined in the work already form part of history, a past which must now be re-examined. Few are more aware of this than the editor, who has the courage to admit in

his prefatory note that "the papers in this collection have to some extent been outdated".

The book consists of 16 essays by different authors covering developments in China since 1949 as seen in its entirety from the western point of view. Between them the authors cover rural development, industrialisation, agriculture, health care and population control, economic planning and trade, environmental protection, women's role in the country's development, forestry, intermediate energy technology, Chinese foreign aid, city planning and the role of the People's Liberation Army. Curiously, the place of science, the very foundation on which China's new history will be written, is relegated to a passing comment.

Often proffered as the ideal model for Third World development, China's growth has provided a burgeoning of material for commentators — so much so that it is often difficult to discern which of the opinions are really derived from Chinese experience and which are merely the theories of development experts. Thus, in a sentence

Every year thousands of biochemists read

Trends in Biochemical Sciences

do you?

If not then you have been missing one of the most imaginative and readable publications in scientific literature today.

In less than four years 'TIBS' has acquired a readership of more than 25,000. This can be attributed to three features which set 'TIBS' apart from any other publication in biochemistry:

Reviews - excellent scientific standards

'TIBS' publishes about 100 reviews a year. Each review is written by an expert and deals with a specific topic. The author brings together recent findings and ideas and puts the whole picture in perspective - making clear its relevance to readers from different areas of biochemistry and related disciplines.

The 'TIBS' format

Each monthly issue of 'TIBS' contains at least 48 pages. 24 pages are devoted to six to eight short reviews and the popular '50 Years Ago' series of historical articles. The remaining pages of each issue contain a wide variety of feature articles, editorials, news, book reviews, letter to the editor, meeting announcements and advertisements.

Readability

'TIBS' articles are written both to inform and entertain at one and the same time. This means that every author writes in a style stripped of jargon so as to be intelligible across the disciplines, from the beginner through to advanced research worker.

DOW UNIFORM LATEX PARTICLES FROM UNISCIENCE

The Perfect Spherical Shape of Dow Uniform Latex Particles makes them versatile enough for:

- Calibrating instruments
- Counting virus particles
- Determination of pore size
- Agglutination tests
- Studies of the reticuloendothelial system.
- Analysis of Flagellate locomotion systems.
- U.S. National Bureau of Standards
- Electrophoresis experiments in space by NASA.

These unique particles of specified diameter, which aid measurement and diagnosis, are also available as:
Carboxylate-Modified Uniform Latex Particles for covalent bonding of antigens, antibodies, enzymes, etc., to the surface of the particles.
Dyed Uniform Latex Particles for improved visibility e.g. agglutination

tests and to permit non-radioactive 'tagging' experiments.

Available in 2ml, 5ml and 100ml quantities at New Reduced Prices.

NICHOLAS COPERNICUS

**VOLUME II ON
THE REVOLUTIONS**

**AN ENGLISH
TRANSLATION
BY**

EDWARD ROSEN

Nich Copernicus

It is nearly 500 years since Nicholas Copernicus, the father of modern physics, dedicated to His Holiness Pope Paul III, his theories on physics in *De Revolutionibus Orbium Coelestium*.

Now for the modern academic, unversed in mediaeval Latin, Professor Rosen has produced a new translation, together with a detailed commentary on the complete Latin text.

This is the 2nd volume in a planned 3-volume set of the complete works of Copernicus organised by the Polish Academy of Sciences. Printed and bound to a very high standard, it is a work of great scholarship and art in its own right, and a fitting companion to Volume I, the full-colour facsimile edition published in 1972.

M MACMILLAN PRESS

such as "Although the domination of science by politics during both these periods had an adverse effect on scientific development and on the economy in general, there was also a growing body of opinion that these massive campaigns were a necessary pre-requisite to generating political will for Mao-style development" (page 219), it becomes difficult to know which growing body of opinion is being considered.

Nevertheless, considerable printing errors apart, this volume of essays will remain a valuable source, as much a reflection of western social ideals in the 1970s, as of China's development. Not unexpectedly, for a collective work by different authors, written at different times and clearly aimed at different levels (a few no doubt originally intended as University lectures), there are repetitions of facts and discontinuities in style which detract from the overall impression of the book. But it does raise pertinent questions in the light of China's present changing policies: can similar development goals be achieved by roads other than that of revolution? The answer today may be very different from

that which seemed obvious not so very long ago.

The re-writing of any chapter of history, particularly when done at a distance, calls for no small amount of self-assessment. Leo Orleans, long respected as an analyst of Chinese affairs, expresses the new western dilemma: "It is possible to feel some regret that her [China's] drastic veering did not settle on some more middle course. Mao's dedication to the creation of an egalitarian society, his "serve the people" ethic, the sense of idealism he attempted to instill in the people, captured imaginations outside China as well as within, and some of those who disagreed with China's politics and policies could still identify with Mao's utopian ideals, [which] set China apart from every other nation" (page 225). By choosing a new and different road to development, China has set not only new goals for itself, but also a whole set of fresh criteria for western analysts. □

M. Christine King is researching into Chinese Affairs and the History and Philosophy of Science.

Higher marine fungi

R. A. Eaton

Marine Mycology: The Higher Fungi. By J. Kohlmeyer and E. Kohlmeyer. Pp. 690. (Academic: New York and London, 1979.) \$59.50; £34.60.

FOR 20 years, the authors' research in the field of marine mycology has produced a high quality of illustration and description of marine fungi, particularly through their *Icones Fungorum Maris* and *Synoptic Plates of Higher Marine Fungi*. A large part of this volume combines the essence of these publications to give us the most comprehensive work since Johnson and Sparrows (*Fungi in Oceans and Estuaries*, J. Cramer: Lehre, FRG, 1961) that any student of marine fungi would need.

More than half of the book comprises illustrated keys, and descriptions of higher marine fungi including 90 plates of micrographs. But is photographic representation the best means of illustration? Certainly the beautifully accurate line drawings in the *Icones* are not surpassed by many micrographs in this book. Their use of interference contrast microscopy introduces a new dimension for observing the appendaged ascospores of many marine fungi, but has its limitations in aiding interpretation of sectioned ascocarps or spermogonia, and non-appendaged spores.

Parasitic and saprobic marine fungi exist on various natural and man-made substrates from mangrove vegetation to polyurethane. They are distributed in different geographical zones and at different depths in the oceans. The book deals very comprehensively with the factors which affect the occurrence of filamentous fungi and yeasts in the sea, but the authors consider only a "selection of pertinent papers" on their physiology and biochemistry.

Other chapters are concerned with methodology, fruit body and spore ontogeny, and the release, dispersal and settlement of spores. The fascinating relationships which exist between fungi and marine animals (particularly marine wood borers) and between fungi and algae (producing marine lichens), are also covered. Apart from a chapter on marine yeasts this book is concerned wholly with filamentous higher fungi, as the title states. For the sake of completeness, was it not possible to broaden the scope of the book a little, and include more than a mention of the lower marine fungi — one-fifth of the total marine mycota?

The authors state that "a major objective of this treatise is to assist students of marine fungi in the identification of species." This is achieved, for it is unquestionably a reference book to be kept on the shelf above the microscope. □

R.A. Eaton is Senior Lecturer in the Department of Biological Sciences, Portsmouth Polytechnic, UK.

OBITUARY

O.R. Frisch, 1904-1979

ON 22 September 1979 Professor Otto Robert Frisch, OBE, FRS, Emeritus Jacksonian Professor in the University of Cambridge, died following an accident. He was a distinguished and original nuclear physicist. His contributions to physics will be, and the example he set in his approach to the subject should be, remembered by future physicists.

Both in physics and in music, which was next to physics his strongest interest, his main driving force was enjoyment of what he was doing. In physics this meant using simple apparatus, preferably designed and made by himself, and looking for important problems with transparent answers. Some of the instruments he made might be called gadgets, but surprisingly often these gadgets were able to provide answers to topical problems. Naturally "big physics" was not his line, and he never became involved with projects needing large machines and large teams of collaborators.

His piano playing was of near-professional standard, but he was not a perfectionist, and was not above listening to, or playing with, musicians of a much lower calibre, provided they shared his enjoyment of the result.

He was born on 1 October 1904 in Vienna. His father, Justinian Frisch, was a printer, his mother a very gifted musician. I do not know whether his father's profession influenced his interest in writing and his flair for the written word, but no doubt his mother encouraged his music. The members of the family were very close, and all his life he remained in touch with his relatives. Above all he was very close to his aunt, Lise Meitner, the famous nuclear physicist.

At school Otto Robert (as he was known to the family; later he was just Robert to his friends, except for the Los Alamos period, when there were too many Roberts around, and he became Otto) showed marked ability in mathematics, and almost chose it as a career, but in the end decided that this would be too abstract for his taste, and he settled for physics.

His studies in the University of Vienna under Professor Karl Przibram appear to have been uneventful, and he obtained his D Phil in 1926, after four years in the university. This was rapid progress, but at the time not unusual. After a year in a small firm run by an inventor, where he presumably could indulge in his love for gadgets, he accepted a post in the Physikalisch-Technische Reichsanstalt in Berlin. His work there was in the optics division, with the assignment to work on a proposed new light standard, but he says "I stayed long hours trying out half-baked

ideas of my own". His assignment was hardly exciting, but he was able to attend seminar meetings at the university, and listen to remarks by Einstein, Planck, Nernst and others. Lise Meitner was there, too. She worked, and lived, in the suburb of Dahlem, but Frisch saw her frequently, to the profit of his physics and his music.

In 1930 he became an assistant to Otto Stern in Hamburg, famous for the Stern-Gerlach experiment. Stern was an outstanding experimenter, not in manual skill, but in his command of the relevant principles and in the design of experiments, and his laboratory was the leading one in the world for atomic-beam research. Frisch worked closely with him and took part in important experiments, including the first observation of the diffraction of atomic beams by crystal surfaces. At the end of his Hamburg period he did his first important experiment on his own, observing the recoil of atoms on photon emission.

But by this time the Nazi government was in power, and both Stern and Frisch, who were of Jewish descent, had to leave. Frisch went to Birkbeck College to work under Blackett with a grant from the Academic Assistance Council. Here he became interested in nuclear physics, which in 1933 was full of excitement. He invented a method of measuring very short-lived activities, and this led to the discovery of some new radioactive isotopes.

A year later, Niels Bohr, who must have heard of his ingenuity in devising and carrying out experiments, invited him to Copenhagen. The next five years in the informal and stimulating atmosphere of

Bohr's Institute were very fruitful. It was the time when neutron physics had been initiated by Fermi's work, and Frisch, too, started on neutron work. Probably he was drawn in initially because he happened to have the most appropriate counter with which to test for neutron-induced activity. He made many important contributions to that subject.

It was in neutron physics that he did his most famous piece of work. He was spending Christmas 1938 with Lise Meitner, who was now in Sweden. She received a letter from Otto Hahn, with whom she had collaborated closely until she had to leave Germany, telling her of his discovery that barium was among the products emitted when uranium was bombarded with neutrons. Hahn realised this meant that the uranium nucleus must have split into two large pieces. Frisch and Lise Meitner were as dumbfounded by this news as all other physicists when they heard of it. But after thinking about the discovery for a while, they understood how the strong electric charge could help to overcome the surface tension and lead to an unstable configuration once the nucleus was set vibrating by a collision. If the nucleus had taken a sufficiently elongated form the mutual repulsion of the positive charges would drive it apart, and this would release an energy of about 200 MeV. Frisch coined the word "fission" for this process. After returning to Copenhagen and composing a letter to *Nature* jointly with Lise Meitner over the telephone to Stockholm, he carried out an impressively simple experiment proving the emission of energetic and heavily ionizing particles from the bombarded uranium, and thus confirmed the interpretation.

Fission was now the exciting part of nuclear physics, and most nuclear physics laboratories started to work on this. Frisch continued in this field, too, and did several more important experiments.

But this was 1939. War was imminent, and Denmark not too healthy a place for a German refugee. (The Anschluss had made him a German subject). Besides, the Danish police were making difficulties about extending his permit. So he tried to find a place in England, and, when Oliphant heard of his problem, he arranged an appointment for him in the University of Birmingham. Here Oliphant was trying to build up facilities for nuclear physics work, but there was not much equipment as yet, and Frisch could not continue his experimental work immediately. But he continued speculating about fission.

The possibility of the release of nuclear energy was then in many people's minds,

once it had been shown that neutrons were emitted after the fission. One was awed by the thought of a new weapon of terrifying power, but Frisch, like others who had understood the paper by Bohr and Wheeler on the mechanism of fission, and Bohr's argument that the fission caused by slow neutrons was due to the rare isotope ^{235}U , were reassured that no violent explosion could happen in ordinary uranium. The thought of separating uranium isotopes in large quantities seemed to belong to science fiction. Then one day Frisch came to me and said "Suppose one had a large amount of separated ^{235}U , what would happen?" One could make a guess at the fission cross section from the ideas of Bohr, and I knew how to estimate the critical size, given the cross section. The answer staggered us by being smaller than we would have guessed. Next we had to estimate how far the chain reaction would proceed before the energy it released would drive the uranium apart. The answer again staggered us by being a reasonable fraction of the total energy available. If that was so, we said, it would be, as a weapon, worth its price, even if the isotope separation plant cost as much as a battleship (this turned out to be an underestimate). What if the Germans got there first and a nuclear bomb was in the hands of Hitler's Germany?

We wrote down our arguments, and that was the start of serious interest in atomic energy work in England. Frisch first tried to explore the possibility of isotope separation by thermal diffusion, but did not get far, and we now know that the thermal diffusion coefficient in the only gaseous uranium compound happens to be practically zero. Instead Frisch moved to Liverpool, where in Chadwick's laboratory there was a cyclotron and other facilities for nuclear physics, and worked on the nuclear physics aspects of atomic energy until the end of 1943, when it was decided to discontinue work in England and move to America those who could be useful to the American work.

So Frisch went to Los Alamos, the strange atom-bomb city in the middle of New Mexico. He was not attached to any specialist team but had a roving assignment and in that way was able to give essential help to many different groups. One of the experiments he set up himself was a typically original scheme known as the dragon. Two pieces of fissile material which together would make a critical mass and so cause a violent chain reaction, were allowed near each other for only a short moment, by dropping one piece past the other. The speed was so arranged that the chain reaction did not develop to any dangerous degree. The name indicated that one was tickling the tail of a dragon. The experiment made it possible to observe details of a near-critical situation which were otherwise hard to get at.

After the war, Frisch returned to England and became head of the Nuclear Physics Division at Harwell. Adminis-

tration was not his favourite pastime, but he found that his deputy Dr (later Sir) Robert Cockburn delighted in running things and did it well. Frisch left Harwell in 1947 to become the Jacksonian Professor of Physics in Cambridge and a Fellow of Trinity. At that time nuclear physics in Cambridge was overshadowed by crystallography and other lines. It was not in Frisch's character to fight for more support. Besides, nuclear physics had now become big physics and less to his taste. While he kept a lively interest in nuclear physics and in the newly developing particle physics, he spent more of his time teaching and writing. Many students profited from contact with his way of doing and looking at things. He still liked gadgets, and made many ingenious instruments. His writing included *Meet the Atoms*, a very readable popular introduction to modern physics. Only a few months ago he published his recollections under the appealing title *What little I remember*,¹ and it is pleasing that he was able to leave this lively record of his personality.

Shortly after moving to Cambridge he married, and there were two children. His wife shared not only his Austrian origin, but very many of his attitudes and his love for music.

Shortly before retiring in 1972 he invented an apparatus for measuring and evaluating bubble-chamber tracks, and he later became a partner in a firm set up to manufacture this. I do not know whether this commercial activity made him a wealthy man, but he clearly enjoyed this novel position and seeing his gadget being produced.

His was a full life, but he just failed to reach his seventy-fifth birthday with its warm messages from his many friends.

Martin Lüscher

IN THE midst of his fruitful work, Martin Lüscher's life was taken on 9 August 1979 by a tragic accident, at the age of 63. He was Professor of Zoology at the University of Berne, and directed its Department of Zoophysiology with scientific foresight and a fatherly concern for his colleagues and students. His name will be remembered by zoologists throughout the world.

Martin Lüscher, son of the Basle artist Jean-Jacques Lüscher, spent a quiet youth in his family home, with extended visits to Provence. There, the harmony and beauty of the landscape created a lasting impression on him; in the balmy

Mediterranean atmosphere with the colour play and diverse insect cacophony in the flower fields he developed a love and interest of plants and animals. In Basel in 1944 he was awarded a PhD in zoology. After his marriage to Noemi Stoecklin, daughter of the Basle artist Niklaus Stoecklin, which proved to be a true life partnership, he began, with her, his life-long progress as a zoologist. They shared a life of work, pleasures and trials. A great deal of his professional success was due to his close accord with his wife, with guests always welcome at their home.

As a young zoologist, Lüscher's first post was as a research assistant in Berne, where he worked under F.E. Lehmann on the physiology of development of amphibians. Soon afterwards he met his great teacher, the insect physiologist, Sir Vincent Wigglesworth of Cambridge, under whom he was able to work. Martin Lüscher saw Wigglesworth as the founder of a new branch of research: experimental insect physiology.

From England Lüscher moved to Paris, where he was introduced to the biology of termites by the renowned termite specialist T.P. Grassé and found the stimulus for what was to become his principal research — caste formation in termite colonies. He wished to study termites in the field as well as the laboratory, and he soon had the opportunity to take part in an expedition to observe at first hand the highly organised termite colonies of Africa. Lüscher was particularly fascinated by the highly elaborate nest structures built by the millions of termites within the colony. He was the first to understand their design as a well planned respiratory system with temperature and humidity regulation, and an air circulation system functioning through the warming of the air inside the nest. After imaginative and productive field work he spent a very important year of study in the United States on a grant from the Rockefeller Foundation. He was given the opportunity to stay for some time with A.E. Emerson, the expert on termite biology and taxonomy, and was then able to acquaint himself with modern methods of insect endocrinology in the leading laboratories at Berkeley, and at Harvard with C.M. Williams. Afterwards he worked at the Swiss Tropical Institute in Basel and in 1954 was appointed professor at the University of Berne. Under his direction the new Department of Zoophysiology was formed.

In 1965 he was appointed to the four-year directorship of the Zoological Institute. During the academic year 1967/68 he was Dean of the natural science faculty and from 1969 a member of the Swiss National Science Foundation. In his last important undertaking, in Nairobi as project leader at the newly founded International Centre of Insect Physiology and Ecology, he set up an enthusiastic research team.

Lüscher carried his title with quiet

modesty. His lectures were simple and clear, and his criticism was always constructive and helpful. His motivation as a researcher derived from the pleasure of observation, an urge for knowledge and a keen understanding of relationships. He was intrigued, like many earlier researchers, by the secretive world of the termite colony. How do all the different castes including the workers, the soldiers and the reproductive individuals develop from the same origin in such numbers? How is this ratio maintained and regulated? His understanding of the termite colony as one organism, which he had gained in Africa, and the methods of experimental physiology he had learned, led to further discoveries. He found that all the castes of the termite colony interact continuously, as though they were parts of a single organism. The presence of reproductives in lower termite colonies inhibits the development of that caste, whereas their absence induces the formation of further reproductives. In a similar way the ratio of developing soldiers is regulated by the proportion of soldiers present in the colony.

Lüscher became aware of the importance of 'social hormones' as agents of regulation and communication within the termite colony, and with the biochemist Peter Karlson he introduced the now well-known term pheromone. He could demonstrate by means of ingeniously simple experiments that pheromones are released from the anus of the reproductive individual and are ingested orally by other termites and then distributed throughout the colony by oral exchange, the so-called process of trophylaxis. Pheromones regulate the make up of the social structure, whereas hormones determine the process and direction of development of the single individual, and the latter are controlled by the former. It was established experimentally that the inhibition of reproductive caste development could be simulated by application of 'juvenile hormone', which in general inhibits the metamorphosis of larval insects into adults. The same hormone applied in higher doses to the termite society was shown to stimulate soldier production. With these findings, Lüscher made a breakthrough towards a new physiological understanding of termite caste regulation. The antagonistic effect of reproductives and soldiers that inhibit the development of their own caste and open the way towards development of the other could be interpreted physiologically: the reproductive castes transmit, by means of their pheromones, information causing the developing larvae to produce their own juvenile hormone, whereas the soldiers, probably also by means of specific pheromones, transmit information to inhibit juvenile hormone.

Recent results from Lüscher's team in Nairobi and Bern suggest similar exocrine-endocrine principles of caste regulation for

the highly organized mound-building 'higher termites.'

To understand all these interrelationships Lüscher augmented his work with basic research into the mechanism of hormonal interaction. He investigated the mechanisms of action of juvenile hormone and the ecdysteroid moulting hormones. He studied the interactions and regulatory mechanisms of those hormones in the cockroach, a nonsocial insect related to termites.

Lüscher's name as a termite researcher and insect physiologist has international acclaim. He retained, however, his love for the countryside, for plant and animal life and for his fellow men. I best remember the hours I spent with him in the African bush, as we stood looking with astonishment at an opened termite mound. Here lay the motivation and drive for his life's work: the questions arising from his awe and respect at the incomprehensible and beautiful. This ethos together with scientific accuracy and genius gave him and his work its far reaching importance.

Reinhard Leuthold

G.S. Adair

GILBERT SMITHSON Adair, who died on 20 June 1979, was a highly respected and well loved character on the Cambridge scene for sixty years. Many generations of students and research workers have cause to be grateful for his willing help with practical advice and theoretical explanations. This ranged from supplying Max Perutz with his first haemoglobin crystals and instructing people in the art of preparing collodion membranes of varying permeabilities, to simple explanations of Gibbsian thermodynamics. In this way he exerted considerable influence although he was, to the best of my knowledge, only formally responsible for the supervision of two research students; Muriel Robinson (who became Muriel Adair) and the author of this notice.

Adair was born on 21 September 1896, the son of a Quaker family. He went up to King's, Cambridge, in 1915 and remained in that city, with only very brief interruptions until his death. He was a Fellow of his college from 1923 to 1933 and an honorary Fellow after retirement from his University post (Reader in Biophysics) in 1963.

The wide interest of biophysicists in haemoglobin, which extended over the last 60 years, involved several distinguished Cambridge men. Adair had the stimulation of A.V. Hill, Barcroft and Roughton, who not only contributed to our knowledge about the respiratory function of haemoglobin, but also used this important

and plentiful protein to develop novel thermodynamic and kinetic methods. The iron contents had given an equivalent weight for haemoglobin of about 16,700 Daltons. Brown and Hill had shown that comparison of calorimetric and van't Hoff ΔH for oxygen binding gave about 17,000g of haemoglobin per mol of binding site. Osmotic pressure measurements preceding those of Adair gave variable results and tended to support the prevailing theory that haemoglobin occurred in solution with a molecular weight of about 17,000 and that there was some tendency towards aggregating of these units. Adair's attention to experimental detail is illustrated in a masterly paper "A critical study of the direct method of measuring the osmotic pressure of haemoglobin" (*Proc. Roy. Soc. A*108, 627, 1924) in which he reports a molecular weight of 67,000 and explains the erroneous results of others. It is important to point out that this preceded by about a year, Svedberg's determination of the molecular weight of haemoglobin in the ultracentrifuge.

Further studies of the osmotic pressure of haemoglobin solutions led Adair to detailed experimental and theoretical investigations of membrane potentials. In the 1930s he extended these studies to serum proteins and to the determination of charges on protein molecules from the measured membrane potential at different pH and ionic strength.

The above contributions led to his election to the Royal Society in 1939. During the war Adair was much occupied with the teaching of physiology, especially in practical classes. After the war, one of his main concerns was to improve his simple technique for measuring osmotic pressures, so that small pressures of solutions of large protein molecules could be measured. He also found it difficult to believe the results of his second research student, which indicated reversible dissociation of haemoglobin molecules in dilute solutions and at high ionic strength, until he confirmed it himself with his refined methods.

Adair was a shy but very friendly man who was absolutely devoted to his rather specialised, but very valuable work in the laboratory. The essence of his experimental technique was simplicity and attention to detail. Old fashioned alarm clocks and domestic heaters formed the backbone of his wonderful method for making semi-permeable membranes.

Apart from his scientific work Adair read widely and, in his youth, was a keen rock climber. There are a number of stories about his climbing activities at college and into the Physiology Laboratory. From 1931 until her death in 1977, he shared a life of work and simple pleasures with Muriel Adair. Their house near Grantchester Meadows allowed him to pursue his interests in the observation of a variety of plant and animal life.

20 March 1980

Using the scientific expertise of the House of Lords

THE idea for a House of Lords select committee on science and technology came from Lords Shackleton and Sherfield last year — shortly after the reorganisation of the House of Commons select committee structure. This reorganisation has dealt a severe blow to the interests of science and science policy in Parliament because each select committee covers the remit of a single government department. Science now comes primarily under the select committee for education and science — instead of the science and technology committee of the old structure — although topics of scientific content may also touch on the interests of other committees such as agriculture or energy.

But the education and science select committee is likely to spend more time on education than scientific matters, and none of the other departments is likely to provide a proper forum for scientific discussion of issues which embrace many departments — like biotechnology, for example. Lords Sherfield and Shackleton proposed a select committee in the House of Lords to fill the gap. Parliament and government were very badly informed on science political matters, they felt, and select committees were an invaluable way of gathering information. A House of Lords committee would also have the advantage that its members could be drawn from the many respected scientists and engineers who sit in the Lords. It should therefore be able to bring more scientific expertise to bear on key issues of science policy than its predecessor in the Commons.

The first indication of its intentions came last week, when the new committee — the 'House of Lords Select Committee on Science and Technology' decided on the first two subjects for its inquiries: forestry and electric vehicles. Two subcommittees are to be set up to consider them: one, under the chairmanship of Lord Sherfield, will look at the role of fundamental research in relation to British forests and woodlands; the other, under the chairmanship of Lord Gregson, will review the case for electric vehicles in the light of present energy shortages.

These subjects are intended to fulfil the criteria laid down for topics of inquiry when the select committee was first agreed: that is they should be of interdepartmental interest, and therefore fall between the interests of several Commons select committees, or they should be of insufficient relevance to any government department to be considered at all.

Forestry is a subject which might easily have come under the Ministry of Agriculture, Fisheries and Food or the Department of the Environment. The House of Lords committee hopes to be able to ask questions which will be relevant to both departments and introduce an interdiscip-

linary approach.

Electric vehicles, on the other hand, might have come under the Department of Energy, but with the seemingly weightier problems of nuclear energy to consider, the House of Commons energy select committee would be unlikely to get round to the subject for a long time. The House of Lords committee may well, in this case, be looking at a worthy topic which might otherwise have been neglected — at least until its topicality had been lost.

Neither of these subjects, however, fires the greatest enthusiasm. They are hardly the most pressing of current issues of science and technology policy. Nevertheless they are both intended to be fairly short investigations: in particular, Lord Gregson's subcommittee on electric vehicles is due to start taking evidence shortly after Easter and to report in the autumn. Further plans are still tentative, although the committee has earmarked "aspects of information technology" and the role of science policy making bodies and their relationship to government as its next subjects for investigation. Specific topics within these broad subjects will have to be identified if useful inquiries are to be made. Under the second subject, for example, a look at the role of the National Research Development Corporation or the Department of Industry's requirements boards could be useful.

However, the committee should not shy away from considering highly political topics. Last week Lord Shackleton said that the committee had been asked "to avoid questions where the political component is much larger than the scientific". But the greater the political overtones of a scientific issue, the more important it is that it should be investigated by a select committee with scientific expertise.

Lord Shackleton also said that the committee would take an interest in "things that haven't been taken into account elsewhere". This could be incisive, if topics are chosen wisely; but it could also be a recipe for bumbledom, particularly if the committee allows itself to be steered away from the politically hot scientific topics.

One possibility that seems to have been ignored is that the committee should use its scientific expertise, and its ability to appoint scientific advisors, directly: why not look in technical depth at scientific issues which are in the province of the Commons committees, but cannot be covered there at sufficient length? Take the question raised by Sir Alan Cottrell recently about the feasibility of guarding pressurised water reactor pressure vessels against dangerous cracks. This is a fine scientific and serious political issue to which the Lords committee could pay profitable attention. □

United States

Gasohol enthusiasm may increase world food problem

A warning that growing enthusiasm for the use of agricultural crops to produce automobile fuels may contribute directly to escalating food costs and shortages has come from Lester Brown, Director of the Washington-based Worldwatch Institute.

In a report financed by the United Nations Environment Programme and the Gund Foundation, published last week, Mr Brown draws attention to potential conflicts between the different users of such crops, arguing that the demand by motorists for fuel produced in this way represents a major new variable in discussions of food supply and population growth.

"The stage is set for direct competition between the affluent minority who own the world's 315 million automobiles, and the poorest segments of humanity, for whom getting enough food to stay alive is already a struggle" Mr Brown says in his report.

The rapidly rising cost of petroleum has made the use of alcohol as a fuel — either in pure form, or mixed with petrol to produce gasohol — increasingly attractive, in addition to its environmental advantages and the fact that its production can provide an important source of jobs in developing countries.

The most advanced gasohol programme is in Brazil, where according to Mr Brown the government has set a target of producing 10.7 billion litres of alcohol by 1985. The US also has an ambitious programme, with grants and tax credits designed to reach a domestic production level of 2 billion gallons of ethanol by the mid-80s.

Plans for developing major programmes are also under way in other food exporting countries such as Australia, New Zealand

and South Africa. The consequence, says Mr Brown, is that the possibility exists for the first time of a major shift of food production capacity to non-food purposes".

Yields can be high, and could be boosted even further by a "modest effort in plant breeding and research" he suggests. As a result, the economic conditions for the large-scale commercial production from high-yielding energy crops appears to be favourable.

But the impact on food supplies and prices could be severe, particularly at a time when increases in world food output are scarcely keeping up with population growth. In Brazil, for example which already has a net deficit of 6 million metric tons a year, meeting official targets could mean planting one fifth of the country's cropland with sugarcane, driving food prices upward and "leading to more severe malnutrition among the poor".

Similarly the US, currently the world's largest supplier of grain, would have to reduce its exportable surplus considerably to meet official production goals, as distillers take a growing share of the US grain harvest. Mr Brown estimates that an individual in the US running a car solely on alcohol would require almost ten times the cropland needed to produce food for an affluent diet. Even using only a 10% ethanol mix, the car owner's cropland requirement would double.

But the solution is not to abandon gasohol. "A carefully designed alcohol fuel programme that gave farmers a first priority in the use of ethanol for tractors, farm trucks, and irrigation pumps would be a major step toward the creation of a sustainable food production system, and of a sustainable society", Mr Brown says, followed over the longer term by a programme based on forest products and cellulosic materials of forest origin. □

Carter: synfuels strategist

Controversy over \$20 billion synfuels programme

AFTER three months of intense negotiation, the US Congress is putting the finishing touches to legislation which will commit the government to spending \$20 billion over the next four years to stimulate the production of synthetic fuels. But the proposed legislation remains surrounded by controversy, in particular over the extent to which political interests have been allowed to override environmental and technical concerns.

The synfuels programme, a major plank in President Carter's strategy to reduce dependence on imported oil, would provide a variety of financial incentives to encourage private industry to construct plants producing synthetic oil or gas from coal, oil shale or other sources.

The proposal has been eagerly pushed by a number of constituencies, such as coal companies and engineering firms, who see it as a potential source of generous government support.

But it still faces a battery of critics, from environmentalists who argue that the health and environmental implications of a crash synfuels programme are receiving inadequate attention, to some parts of the oil industry which feel that a massive federal investment, based primarily on existing technology, could seriously distort the future growth of the industry.

So far the environmentalists have received little comfort. They have raised numerous concerns, such as the large quantities of water needed by synfuel plants, and the potential carcinogenic

hazards arising from the emission of aromatic and hydrocarbon amines. But legislators have indicated that they are more concerned about producing energy than meeting social and environmental costs — and are unlikely to produce much extra money for research into the latter.

Neither has much been done to calm the fears that a programme on the scale envisaged by the administration — initially aimed at producing 500,000 barrels a day by 1985 and 2 million by 1990 — is overambitious, and likely to encounter problems such as an inadequate technology base and a severe shortage of appropriately qualified scientists and engineers.

Typical reservations were expressed at a two-day meeting organised last October by the National Academy of Sciences, and attended by a cross-section of industrial and academic scientists and engineers. This reached the conclusion that the 1985 deadline could not be met, but would require six to eight years to achieve.

The meeting also pointed out that reaching the 1990 target would require second stage technologies to be selected before the results of the first stage had been properly analysed.

Following these and other similar

criticisms, the administration's initial proposals have been tempered. Thus the President has agreed that the initial cost of \$88 billion be broken down into two stages, with Congress committing itself only to \$20 billion in the first four years.

Following widespread opposition from the oil industry over what it considered to be excessive federal involvement and unfair competition, the president has also agreed that the synthetic fuels corporation which will be responsible for the programme will not have the authority to construct and run its own plants, but merely assist the private sector to do so.

Furthermore members of the Senate and the House of Representatives, meeting last week to resolve differences in their respective versions of the synfuels legislation, agreed that the deadlines for the 500,000 and 2 million barrels a day targets be set back to 1987 and 1992 respectively.

But the major thrust of the administration's strategy of pushing for ambitious production goals remains in place. These goals had been strongly supported by the Senate, but opposed by the House which had proposed a more modest package — costing only \$3 billion and with no new corporation — and

suggested a greater emphasis on conservation measures to meet the same goals.

As far as manpower needs are concerned, Dr Alex K. Logwunik of Pullman Kellogg, one of the largest engineering firms in the country, estimated last month that the proposed synfuels programme could absorb 20% to 60% of the capacity of the ten major engineering firms in the country. And he warned that the result could be a series of shortages of qualified personnel, already beginning to affect other areas of energy technology.

Supporters of the synfuels programme, however, argue that similar claims had been expressed before other large-scale national efforts, such as the Apollo moon landings. And that once the programme is under way, it will stimulate a flow of research workers and technical people from other areas.

Critics are unconvinced. But in an election year both Congress and the White House are keen to be seen to be doing something about the energy problem — and responding to the frustration of constituents takes precedence over the finer logic of technological timeliness.

David Dickson

Split over nuclear export licensing

FACED with growing difficulties in implementing its non-proliferation policies, the Carter administration is seeking to simplify its task by removing an independent check on the adequacy of safeguards covering nuclear export currently provided by the Nuclear Regulatory Commission.

The NRC itself is split over whether such a move is desirable, but it is being strongly resisted in Congress, for in passing the Nuclear Non Proliferation Act of 1978, legislators specifically invoked the NRC to try to prevent the non-proliferation debate from becoming too politicised by remaining within the sphere of the State Department and the White House.

Under the terms of the Act, the NRC is required to evaluate whether facilities to which nuclear fuel or technology is being exported contain sufficient technical and institutional safeguards to ensure that neither could be diverted to military purposes. However its decision to reject a license application can be overturned by the President — whose decision can in turn be reversed by Congress.

In recent weeks, the White House has been faced with a number of sensitive decisions on nuclear exports. Some in particular have been the direct result of the two-year time limit imposed when the Nuclear Non-Proliferation Act was signed in 1978, requiring nuclear shipments to be cut off after 10 March 1980 to all countries which had not renegotiated nuclear agreements along the lines of the Act.

Attempts to enforce controls on the export of enriched uranium to Europe,

however, were bitterly resisted by leaders of the European Economic Community in the summer of 1978, particularly because of the restrictions placed on the transfer of fuel originating in the US.

With the US administration's failure to generate a consensus behind its general strategy at the International Nuclear Fuel Cycle Evaluation (INFCE) meeting in Vienna last month, it is reluctant to provide further embarrassment.

So, last week President Carter agreed that, rather than bring an embargo into effect, western nations would be given permission to continue buying American enriched uranium as reactor fuels, even though they have not complied with the terms of the 1978 Act. The dispensation is allowed for one year, under the President's power to allow exemptions while negotiations are taking place.

A more difficult case is raised by India, which has persistently refused to sign the Nuclear Non-Proliferation Treaty or to accept international inspection of its nuclear facilities — two requirements for being granted export licenses under the 1978 Act — as being unwarranted interference in internal affairs.

The Administration is being pushed by Congress and environmental groups to maintain a firm line in refusing to grant export licenses covering a shipment of 21 tons of uranium for nuclear power plants at Tarapur in India. Under the terms of the Act, nuclear shipments are now banned unless the President determines otherwise.

However, President Carter is thought to

be actively seeking ways of not offending Mrs Gandhi, indicating last week that he is now merely seeking assurances that the fuel will not be used for explosives, rather than any broader commitment — a decision that would probably be accepted by Congress.

In a separate domain, the US is actively engaged in trying to persuade Switzerland not to export to Argentina a facility capable of producing heavy water, which the administration feels could, as in India several years ago, be used to help produce weapons grade plutonium.

Officials in Washington are said to be worried not only about the fact that this would make it easier for Argentina to construct its own nuclear weapons, but also about what they see as a lax attitude by the Swiss authorities in demanding looser safeguards on nuclear exports than had been agreed in 1978 among the main supplier countries — including Switzerland.

Finally the US has so far been unable to get very far in developing an aid package acceptable to the Pakistani government which would both guarantee Pakistan adequate protection against any Soviet threat but also persuade it to give up its attempts — still denied by Pakistani officials — to produce a nuclear bomb.

Faced with these interlocking problems, Mr Gerard Smith, Assistant Secretary of State for non-proliferation issues, has been actively lobbying Congress for a change in the legislation that would remove the NRC from, as one state department official puts it, "second guessing the President on foreign policy issues". □

The Netherlands

IN an energy memorandum designed to foresee the country's needs until the beginning of the next century, the Dutch government has recommended a drastic reversal of its post-war policy to run down coal production. From a pre-eminent position in 1955, when coal contributed 96% of power plant fuel, the mining industry declined as natural gas fields came on stream in the sixties and early seventies. By 1975, coal contributed only 0.7% of the country's power plant fuel stock, and even after the 1973 oil crisis (which led to the re-opening of mines in the south of Holland), it still contributes no more than 6%.

Now the government intends to boost coal production to a level where it supplies 40% of power plant fuel (12 to 14 million tonnes of coal a year) by the year 2000. Gas and oil, which currently account for 90% of power plant fuel, will be restricted to a 20% contribution, and a decision on where the remaining 40% can be found will be delayed at least until 1983.

At present there is an over-capacity in Dutch electricity generation, but this will disappear gradually as older plants are taken out of operation. Of the country's total of 15,000 MW installed capacity, 520 MW is nuclear, and although the government made a decision in principle six years ago to install three more nuclear

Dutch to fall back on coal

plants, discussions on specific proposals are expected to occupy at least two or three years yet.

An increased role for coal in industry is also foreseen in the memorandum, which talks of fluidised bed combustion accounting for the use of five million tonnes of coal in the year 2000. This is expected to require an investment of at least 1½ billion guilders (£1 = 4.4 guilders).

Eventually, new technologies of *in situ* gasification and hydraulic mining will be needed to exploit the 100 billion tonnes of coal lying beneath the entire country at currently non-viable depths of 1,000 to 6,000 metres. In the meantime, an investment of three billion guilders will be required for the gasification of 7½ million tonnes of coal annually for industrial fuel and chemical production.

This coal gas will also be used in a mix with high-calorific North Sea or Algerian gas, or even burnt in power stations — an area in which Shell and the utilities have already taken an initiative.

In a separate report, a group of Dutch industries has concluded that the role of

coal should be even bigger than the government intends, and they call for an expenditure of 25 billion guilders (in contrast with the official estimate of 10 billion) to get the coal industry into gear by the turn of the century. They want reserves to be re-exploited at a quicker pace, and they urge demonstration projects in gasification and fluidised bed combustion within the next two years. To see this combustion revolution on its way, the industrialists suggest, Holland should have a national energy fund and a special under minister for energy (which at present remains in the portfolio of the Minister for Economic Affairs).

A corollary of both the government's and the industrialists' dreams for Dutch coal is that research and development will be required to ensure that the environment remains as clean as it is currently on a gas-dominated energy regime. Anticipating an increase in coal use from 1½ million tonnes now to 26 million tonnes a year by the end of the century, the government is setting up a national R&D programme to concentrate on atmospheric problems, pressurised fluidised-bed combustion and coal gasification, while applications will be explored for flue gas desulphurisation work already carried out elsewhere.

Altogether, the research effort will cost 750 million guilders over the next five years.

International exchange

Scientific forum was not a great success

LAST month's Hamburg Scientific Forum was probably the first and last of its kind. For while the two-week meeting was useful as a platform for western participants to air their views on human rights, and for the eastern bloc served as a reinforcement of the notion that detente is still a going concern, it was in scientific terms virtually useless.

Certainly the UK government was unimpressed by the event. Speaking in the House of Lords, Lord Trefgarne has said that while "a number of useful conclusions" were reached at the forum, he could not give any general assurance about support for future meetings.

Earlier, the UK delegation said in its closing statement that the "practices and processes of the Conference on Security and Cooperation in Europe" were hardly suitable for establishing a framework of scientific meetings. Soviet participants were so embarrassed by the human rights debate which dominated the forum that

they are likely to demand strict limits on the agenda of any future meeting. In the event they will probably be saved the trouble. Member governments meeting in Madrid later this year are likely to shelve proposals for another forum.

While it lasted, the forum brought together well-staffed national delegations of experts prepared to put their heads together in order to discuss "interrelated problems of common interest" in medicine, the human environment and urbanisation. What they produced was not always original thought, but it was interesting as an indicator of the divergent paths seen by different countries as solutions to broadly similar problems.

The energy group, for example, found that the participant countries interpreted "alternative energy" in widely different ways. To the Soviet Union it meant primarily nuclear energy, with the emphasis on fusion research. Sweden stressed energy from biosystems, while Professor P. Boger (West Germany), urged the biological production of hydrogen as a means of using solar energy.

The food production group was hardly revolutionary in its findings, and called simply for "sustained R&D efforts in all aspects of the food system". International cooperation, it decided, was particularly needed in the development of plants with higher photosynthetic capacity, more efficient capability to use available mineral

nutrients and better ability to withstand environmental stresses. In particular, international efforts are needed in identifying and preserving plant and animal germ plasm in the natural ecosystems. More comprehensive gene banks should be set up "to preserve genetic materials for the benefit of plant and animal production in the future".

The medical group, dealing with cancer cardiovascular and virus diseases stressed the need for data sharing and the avoidance of unnecessary duplication. Further international cooperation, they found, is needed in such fields as standardization of diagnostic materials, recombinant DNA (including safety regulations and the evaluation of benefits) and large-scale studies (e.g. drug trials) where insufficient patients would be available in a single country.

Large-scale surveys of this kind, with comparison of the patterns of change in different countries were also urged by the social science (urbanisation) group. They suggested a regular programme or scientific review conferences and seminars, with special emphasis on the interdisciplinary approach. Yet, not even this group, keen as it was for meetings, suggested that a further 'scientific forum' was the appropriate setting. Rather, it suggested, the proposed meetings should take place under the auspices of UNEP, the ECE or UNESCO. □

United Kingdom

US carcinogen regulations urged in UK

ANIMAL tests should be relied on to indicate whether a chemical will be carcinogenic in humans, says a trade union document on occupational cancers published last week.

"When it comes to the interpretation of test results" says the document "the UK guidelines fall far short of their US counterparts. It is stated in the US guidelines that a positive result in animal tests is to be accepted as evidence of human carcinogenicity. Not so in the UK guidelines, where it is stated that 'extrapolation is a difficult procedure'".

Produced by Britain's half-million strong Association of Scientific Technical and Managerial Staffs, the report was launched at a press conference by ASTMS General Secretary, Clive Jenkins. "Too many of our members are dying" he said. "Tens of thousands of new chemicals have been introduced to the workplace since the war. Companies have acted irresponsibly. We want exposure to carcinogens reduced to zero. We want a new approach in law."

Sheila McKechnie, ASTMS Health and Safety Officer, said that her union "was not attempting to ban all chemicals". Of 7,000 or so chemicals that have been tested so far, says the report, "only 600-800 have shown any evidence of carcinogenicity".

Epidemiological studies — or 'body counts' as the report calls them — come too late: "keeping track of the effects of new (and existing) chemicals by observation of the effects on workers — if relied on exclusively — turns the work place into a giant laboratory for the conduct of an experiment in carcinogenesis. No trade union can accept this."

The evidence is that animal carcinogens are human carcinogens, says the report. "Even if subsequent research unearths some exceptions to this rule, it must be taken as a conservative regulatory principle, that is a principle erring on the side of safety. To refuse to accept the evidence of animal bioassays means, in practice, to insist on counting bodies as the only valid method of identifying carcinogens. This is the position usually adopted by industry — especially an industry threatened with the banning of some profitable commodity."

ASTMS is demanding a comprehensive licensing scheme for toxic substances. Under the scheme:

- Only potentially useful substances should be submitted for test.
- The tests should be carried out in public or independent laboratories and financed by a general levy on the industries supplying the substances.
- Only substances which pass these tests should be licensed for commercial use, subject to safeguards dictated by the results of the toxicity tests.

Jenkins: would love health strike

● All companies handling licensed substances should be compelled to keep comprehensive records.

The process of awarding compensation should also be completely overhauled, said Jenkins. "Some firms have internal compensation. We are urging our members not to accept it. One firm — I don't want to name it — went to a man on his death bed and persuaded him to accept the firm's compensation. He would have done much better in the courts."

ASTMS recommends that 'occupational cancer' be recognised as a broad category of industrial disease, and that cancer victims should be automatically entitled to compensation if they can show they were exposed to a known carcinogen, or were involved in an occupation that clearly shows an elevated risk of cancer. The scheme could be funded by a specially flouted National Cancer Insurance scheme, drawing on both public funds and general levies on industry. "There is great sympathy in the Trades Union Council for our views" said Jenkins.

Would ASTMS take strike action over

this issue? "I'd love a strike over health" said Jenkins.

However, the US regulations urged by ASTMS are themselves under pressure, as reported in *Nature* (24 January, page 320). In the latest proposals of the US Occupational Safety and Health Administration, it is expected that the list of 'category 1' carcinogens (ones where scientific evidence of carcinogenicity is strong) will have only 150 chemicals, and only 10 of these a year will be selected for 'special attention'. US industry still feels the regulations to be too restrictive, while unions are attacking OSHA for lowering its sights.

At its press conference, ASTMS was attacked on the scientific basis of its report, which claims that 20-40% of cancers can be traced to occupational causes or synergisms. In particular two of its sources have been roundly attacked: Samuel Epstein's book, 'The Politics of Cancer', and a joint report of the US National Cancer Institute, National Institute of Environmental Health Sciences, and the National Institute for Occupational Safety and Health, titled 'Estimates of the fraction of cancer in the US related to occupational factors'.

However, said Sheila McKechnie, ASTMS did not want their recommendations to stand or fall on technicalities. If the proportion was 40% or 5% it was still too much.

So how will British industry respond? "We are trying to get unions involved in testing these chemicals, to make sure they are unbiased" said Sheila McKechnie. "Initially testing will have to be done in industry; but so far we have met no resistance from companies on the pre-testing of new chemicals. It's chemicals where companies are already deeply involved where there is a problem."

Robert Walgate

Coal produced electricity the cheapest, says US economist

AN American energy economics consultant who waged a successful environmental battle against the emissions of coal-fired power stations in the early 1970s argued last week that electricity produced from coal in the late 80s will be cheaper than nuclear electricity. If he were right, break-even would only occur in the UK if coal tripled in real price over the next eight years.

The consultant, Dr Charles Komanoff, presented his views at a joint session of the Parliamentary Liaison Group for Alternative Energy Strategies and the

environmental group Green Alliance. (Parligaes is a rapidly growing association of MPs and others designed to provide a source of information in the House of Commons alternative to that of the national energy bodies in the case of electricity, largely the United Kingdom Atomic Energy Authority and the Central Electricity Generating Board.) Later, Komanoff gave evidence before the House Select Committee on Energy.

In both fora, Komanoff based his argument on an analysis of capital cost escalation in the 162 power plants built in

the US between 1971 and 1978. Of these, 116 were coal plants, and 46 light water reactors (of which 33 were pressurised water reactors — PWRs).

Over this period the coal plants suffered a real cost increase of 68%. Almost all of this increase, said Komanoff, could be accounted for by new apparatus to control emissions, such as SO₂ scrubbers (half the increase), improved efficiency in electrostatic precipitators and the like.

The nuclear stations built over the same period became more expensive at almost twice the rate. They increased by 128% in real terms.

"If we are to project these trends" said Komanoff "we need an hypothesis for the increases". In the coal case, the reason was environmental controls. In the nuclear case, "it is impossible to attribute specific costs to specific controls, as regulations ripple through the whole plant". The provision of emergency core cooling, a containment vessel, protection against fire, the provision of monitoring instrumentation, protection against seismic events — all had their effect on costs, he said.

A further hypothesis, he suggested, was that regulations become increasingly stringent to hold down total environmental costs. If the number of coal stations were doubled, there would be demands to halve their emissions. The same applies to nuclear power, Komanoff believes "to keep total risk constant, the probability per reactor of an accident must fall".

In both the coal and nuclear case, he calculated, station costs increased by 50% for each doubling of the corresponding sector.

Moreover, the lessons of Three Mile Island have yet to affect power station costs. "The Kemeny findings are not the end of the story. The Nuclear Regulatory Commission, and the Advisory Committee on Reactor Safeguards are constructing proposals which will lead to sweeping, thorough, and comprehensive improvements in reactor design." These alone would continue the upward trend in nuclear costs "and if a Welshman sees certain safeguards applied to a reactor in Virginia, he will want them in Wales too".

In the UK, coal station costs would also rise, thought Komanoff, because "at the moment you export all your SO₂ to Scandinavia and Germany" so there would be pressure for controls, but this would not be so strong as the purely internal pressure in the US — which has now had its major effects.

The net result, he said, was that a 1150 MW nuclear plant built in the US in 1988 would produce electricity at 4.74 cents/kWh. A 300 MW coal station built at the same date would produce electricity at 3.83 cents/kWh, allowing for interest on capital costs. The capital costs would be: nuclear, \$1684/kW; coal, \$945/kW.

But, said David Widdicombe, QC, who was chairing the Parliagaes/Green Alliance meeting, the crucial question was

whether there were reasons to expect the British experience to be different.

There were, said John Jukes of the CEBG. First, progress towards the coal production targets of the National Coal Board were slow; and coal will be needed for other purposes (such as substitute natural gas), pushing its price up. "The US has plenty of cheap coal, so relativities are bound to be different". But, said Komanoff, even a tripling of coal costs would only equalise coal and nuclear electricity prices.

Further, said Jukes, the UK has an appalling record on large construction sites and "until we get that right no-one will know the costs."

"Also the regulations in the US have been piled on one after the other in a not very efficient way." Britain should avoid a detailed licensing procedure like that in the US, said Jukes, where every component has to be certified.

"We won't know the costs until we place the orders for the next advanced gas-cooled and pressurised water reactors" said Jukes, backed up in this by a colleague Mr F P Jenkin, head of the system planning branch of the CEBG. "The CEBG has no commitment to build plant which are too expensive" said Jenkin.

However, a broad call was made at the meeting for the CEBG to expand on a term in its own costings, prepared for the meeting by Mr Jenkin, where the whole cost advantage of nuclear stations comes in a single item: 'net system savings'. (See table). This term contains most of the important assumptions, said Komanoff; will the CEBG not spell them out?

"There is a strong feeling in this meeting that more information is needed" said Widdicombe. "I will certainly accept that" said Jukes.

On the other hand David Pearce, of the Department of Political Economy,

University of Aberdeen, and a prominent critic of the Windscale inquiry into the expansion of nuclear fuel reprocessing facilities in Britain, attacked Komanoff's own assumptions. "The average load factor for a coal plant in the US is 55%, not the 72% he assumes. And I found his results are very sensitive to coals costs. If coal rose to three times uranium costs, his coal/nuclear balance would be reversed."

At the Select Committee on Energy, Komanoff was also subjected to close criticism. "If nuclear reactors are uneconomic" asked Arthur Palmer "why do the utilities continue with them?" Because, said Komanoff, they feel they are fighting a holy war. "But does that eliminate the profit motive?" asked Palmer. There is no profit motive, said Komanoff, because utilities' profits are guaranteed by state law, which guarantees an electricity rate which will cover running costs and give a return on capital investment.

Komanoff recommended that if Britain were to have an expanded nuclear power programme, it should not chose the PWR. There are more PWRs in the world than any other reactor type; "and if you leave yourself open to design reviews of PWRs the world over, you will constantly face escalating costs. On the other hand if you go for a minority reactor . . ."

"If I wanted to destroy the CEBG's nuclear programme" said Komanoff "I would recommend a large Westinghouse PWR". The average load factor of the 13 such reactors over 800 MW in the US was 44% last year. "And over 50 reactor-years the average load factor has been only 52%."

Smaller coal plants, of 200-400 MW, said Komanoff, should be able to operate at 70-75% "if the electricity supply system were properly planned".

Robert Walgate

Table: net effective costs of new stations (March 1980 prices)

	Nuclear			Coal Fired		
	(a)	(b)	(c)	(a)	(b)	(c)
Capital cost of station including initial fuel (£/kW) in the case of nuclear	850	1000	1150	416	490	564
Net effective cost (£/kWpa)						
Capital charges	71	84	97	35	41	47
Decommissioning	2	2	2	0	0	0
Other operating costs	12	12	12	10	10	10
Net system savings	-121	-121	-121	-30	-30	-30
Total	-36	-23	-10	+15	+21	+27

Notes:

- For both nuclear and coal fired stations, (a)×(c) represent -15% and +15% respectively on the central estimate of capital cost.
- Capital charges include those on associated transmission works.
- Capital charges include the annuitisation of interest during construction.
- Decommissioning costs include plant scrap value allowance.
- Other operating costs cover salaries and associated costs, repair and maintenance, rent, rates, insurance, etc.
- Net system savings are system savings after deducting station fuel cost.

NEWS IN BRIEF

Aid recommended for nuclear test victims

NUCLEAR weapons testing probably resulted in "a small number of cases of death or disease" among those living downwind of the test sites in Nevada during the 1950s and early 1960s, for which the government should be prepared to take responsibility, according to press reports of an investigation carried out by a White House study group.

A local paper in Nevada, the *Desert News*, said that the study group's 57-page report, currently under "active consideration" according to White House officials, recommends that legislation should be drafted to compensate those who may have developed cancer as a result of the testing.

However the group is said to oppose legislation proposed by Senators Edward Kennedy and Orrin Hatch conceding liability for radiogenic cancers among residents of the fall-out areas during the period of the tests with courts directed to set the damages payable. The group argues that a more restrictive proposal should be worked out.

Over 950 current and former residents of states surrounding the testing region have already filed over \$2 billion in claims against the government for injuries which, they claim, are directly related to the testing.

Inflexibility of Delaney Clause criticised

DR DONALD Kennedy, until recently commissioner of the Food and Drug Administration and currently provost of the University of Stanford, last week criticised the Delaney amendment — which forbids the use of any chemicals in food shown to have caused cancer in laboratory animals — as being too inflexible and in need of revision.

Dr Kennedy said that the clause in the FDA's authorising legislation codifies the hypothesis that there is no threshold

concentration below which a chemical does not cause cancer. And although this hypothesis "probably holds most of the time", Dr Kennedy said that he was "as certain as I can be of any scientific prediction that some day, very soon, some compound will be demonstrated to have a threshold level for cancer causation."

The Delaney clause was a good version of how society should deal with such risks, he said, but was suffering because of its inflexibility, leaving no room even for a convincing scientific demonstration that there is a safe level for some cancer-causing substance.

"Any law that purports to deal with science ought to leave room for scientific progress," said Dr Kennedy. "For that reason I favour altering the Delaney clause and similar provisions to reflect presumption rather than certainty — a presumption of risk that could be rebutted by a scientific showing that a certain level is indeed safe, or that the use of a particular kind of experiment actually overstated the risks."

Cracks discovered in reactor turbine blades

CRACKS have been discovered in the turbine blades of ten nuclear reactors constructed by the Westinghouse Corporation. Company officials point out that, since the turbines operate totally outside the nuclear plant, they are not considered to present a major source of safety concern at present.

Critics, however, claim that if a turbine disintegrated as a result of the cracking, fragments of steel blades could seriously damage the reactor vessel or a safety system. The Union of Concerned Scientists has asked that plants where serious cracks have been found should be shut down immediately for inspection.

The US Nuclear Regulatory Commission has identified cracks in the turbines of ten reactors, and has drawn up a list of 19 reactors that should be inspected for cracking during the next scheduled shutdowns. The commission is currently studying whether an earlier shutdown is warranted for any of the reactors.

ESA countries approve Spacelab cost overruns

THE member states of the European Space Agency voted unanimously last week to reaffirm their commitment to complete the Spacelab programme in spite of cost overruns. Under the initial Spacelab agreement, member states retained the right to withdraw from the programme if cost overruns exceeded 20%. The Spacelab programme board last week approved a further funding up to a 40% over-run after which another vote can be

taken. Only Italy decided to reduce its contribution (from 18% to 1%) and the remaining ten states have assumed the increased cost. The 1980 Spacelab budget now amounts to \$304 million.

In the meantime UK space scientists have raised objections to the Science Research Council's rejection of Spacelab experiments in the last round of budget applications. "They are reluctant to recognise that space experiments are costly. If this keeps up the UK will lose its expertise in building space hardware," said one of them. An SRC official said that the SRC judged every experiment on a cost effective basis — "it's a question of value for money".

Violence, barricades and arrests at Plogoff

MILITANT demonstrators barricaded all roads into Plogoff recently — the Brittany town in cap Sizun where a complex of four nuclear reactors is to be sited — after Mme Amelie Kerloc'h, deputy mayor of Plogoff had asked the townspeople "to make the commune an island inaccessible to the police". The barricades followed a week of confrontation with a 600-strong police force in which police bombarded demonstrators with teargas grenades thrown from helicopters and the demonstrators countered with Molotov cocktails and stones against massed police formations. An explosive charge damaged the Loc'h bridge and 14 demonstrators, all young workers from the vicinity, were arrested. A delegation of mayors and elected officials from the entire cap Sizun region has demanded the withdrawal of the police as a first step to defuse the situation.

US publishes science magazine in China

THE first issue of a new Chinese language science and technology monthly, *Science and Technology Review*, was launched last month in Beijing. Published by the Education and Science Society in the US, the magazine is edited by US scientists and overseas Chinese scholars including C.N. Yang, Professor of Physics at Stony Brook and winner of the 1956 Nobel Prize in physics. 100,000 copies of the first issue are being sold in 29 municipalities, provinces and autonomous regions. The 104-page first issue includes articles on comparative economic systems — Japan, Yugoslavia and the USSR — and an interview with Sheldon Weinberg and Steven Glashow winners of this year's Nobel prize in physics. According to Xinhua, the Chinese news agency, the magazine, which is the first foreign publication to be given wide circulation in China, is to be given special attention by "the decision-makers and administrators of the state".

FEATURE

Mahler's revolutionary study

THE 1970s saw a debate on the role of science and technology in the economic and social development of the Third World. The failure of the development strategies propounded during the fifties and sixties had become clear. It has been repeatedly pointed out that the benefits of development programmes are not filtering through to the poor majority; western technology often helps to perpetuate rather than reduce economic and social injustice.

No international organisation has taken this to heart more than the World Health Organisation (WHO). This is ironical, because WHO is probably the best and most respected UN organisation in terms of technical competence, and this competence lies in western-style health technology.

But WHO has now set the goal of 'health for all by the year 2000', and to achieve this, it is no longer advocating big hospitals, sophisticated medical technologies, and specialist medical professions. It is now talking about

The UN General Assembly recently approved the World Health Organisation's goal of health for all by the year 2000. Here, the architect of WHO's new policy, Director General Halfdan Mahler explains his thinking to **Anil Agarwal**

concepts like primary health care which are based on such hitherto taboo ideas as community participation in health services, self-coping and self-care, appropriate technology for health, appropriate health cadres like 'barefoot doctors' and traditional medicine. The UN General Assembly endorsed WHO's new goal and its strategy of primary health care in November. All governments are now being asked to formulate by June strategies to achieve that goal.

The radical change in WHO's approach

to health care has been described as the 'Mahler revolution'. Director General Halfdan Mahler has been a major force in the recognition that past health strategy has failed to bring any organised form of health care to more than half of the world's population living in rural areas and urban slums.

But the attempt at change has produced resistance. There is very little real political commitment, either in the developed world or amongst the elite of the developing world, to do much for the poor. WHO now finds itself saddled with idealistic international resolutions that few countries are really keen to implement back home, whether it is in terms of coming forward with the funds required to bring health care for all, or in terms of implementing those strategies and re-ordering domestic health priorities.

Lack of a real constituency is not the only problem. Even to prepare the intellectual framework for the change has meant antagonising such powerful actors

in the existing health drama as the drug industry, the baby milk powder industry, the tobacco industry, and not least, the medical establishment. The latter exists within WHO itself. Convincing WHO's own secretariat of the new mission has not been an easy task; Mahler ruefully refers to his "electric chair".

Mahler was frank about how WHO is coping with the stresses and strains of this change.

"The constitution of WHO speaks of health as a human right; that physical, social and mental well-being should be at the highest possible level, so it was in the constitution of this organisation that it should have not only a narrow technical mission but also a social mission. This social mission was, however, neglected. In the 1950s, we had the post-war hangover, the white man's guilt complex, that something ought to be done about the poor world. Isolated technical assistance programmes — lollipops, as I call them — were developed. Everybody tried to do his missionary activity in the Third World, including me. WHO did some excellent technical work but in a number of rather narrow fields. Then came the reckoning in the 1960s that it is all very well to do a little bit of malaria control, some little work on some other communicable disease, but it doesn't get health down to the grass-roots. So in the 1960s we had agonising questions such as: can WHO assume its real social mission?"

Mahler's strategy to bring the social mission to the fore has been simple: "I felt that the most important thing would be to invite the member-states to take their responsibility, whether they came from the North or the South. The big words, the collective decisions in the political organs of WHO, could no longer remain dead letters. This meant that the member-states had to ask WHO to be their bad conscience. We challenged them with the idea of health for all by the year 2000. It was not shot down in flames. The view was expressed that this indeed ought to be our aspirational target. This then raised the question: what should be the tool in moving towards that goal? That led to the Alma Ata conference on primary health care (PHC) in 1978 and the charting of the primary health care approach."

"There is now", according to Mahler, "in the governing bodies of WHO a realisation of what this movement towards health for all could become. Member states, however, often tend to forget individually what they have decided collectively".

The health debate has focused on two types of contradiction, says Mahler: "First, the conceptual contradiction. Previously we never dared to say that the end-product, health, should be attainable by everybody. We only spoke of services. We said we will try to get as big a coverage of services as possible.

"We have only a marginal degree of

popular participation in health care. This is the fundamental contradiction: if health doesn't start with the individual, the home, the family, the working place, and the schools, then we will never get to the goal of health for all. Even if we take the example of the industrialised countries, self-care, self-responsibility, self-coping in the individual, family and community, represent 50-60% of all care. Unfortunately, health professionals are rarely willing to trust people to such an extent that they acquire power to make the decisions that have to do with their own health. I just don't believe that anything in the North, for instance, can truly be changed when it comes to overeating, overdrinking, abuse of drugs, overstress

‘If health doesn't start with the individual, the home, the family, the working place, and the schools, we will never get to the goal of health for all’

and alienation, if we do not give power to the people to understand their own predicament, and then make conscious decisions about where they want to go."

In every country there is this fundamental contradiction between people and the medical consumer markets that they are provided with. "Of course", says Mahler, "the consumer markets in the developed countries are better because there you find, for instance, drugs all the time. That is because that is where the profits are. But if you go to a developing country, you find drugs available only for 3-4 months a year, which does not exactly generate confidence in the health services. Now by first looking at people's needs we know that we can no longer talk about putting drugs at random into the market. We must have a national policy whereby certain drugs are available all the time. Then we know we can get penicillin for the kid whenever he has pneumonia."

The second major contradiction is that the health services like to deal with only the top 10% of the health pyramid. Medical education is such that it teaches the new professionals to love the highest technology and medical research and development is such that it likes to generate only the highest technology. Resource distribution in the medical sector is such that 80-90% of the resources go to meet 10-15% of the health problems."

In his speeches to the World Health Assembly, Mahler has repeatedly emphasised the need for a strong political commitment if these contradictions are to be resolved. They can be found everywhere in the world. "I have been in two developing countries in the last few months," explained Mahler. "In one of them, the head of state asked me for help in fighting the vector the mosquito. I replied:

'Mr President, indeed we have been trying to do that, but I do not think that we have vector control programmes that can prevent what is probably more important to you, that is, 100,000 or more kids dying from malaria every year. So by all means fight the vector, but let us not forget that it is somehow more important for people that 100,000 of their children will die this year from malaria.

"Now this is not a play on words. By focusing on the vector, we could easily bypass our political responsibility. (The first thing that ought to be done is to organise a system through community participation, if necessary, by which everyone who has or is likely to get malaria can easily get a tablet to prevent it or cure it).

"In the other country, the prime minister asked that WHO's entire budget for two years be used for buying a body scanner. For the same money that country could immunise its children against measles thus saving half a million children dying in the next ten years."

But what is actually happening in the health ministries of the Third World? "I am not speaking of any miracles happening, but I am convinced that there is a reappraisal going on in many developing countries. This is setting into motion within these countries strong confrontations." WHO's role, as Mahler sees it, "is to enable member-States who find it politically difficult to cope with these confrontations to make use of WHO's neutral platform to cope with them.

"Look, for instance, at drugs. It was very difficult to get a national drug policy going in the developing countries because of the resistance, whether it came from the medical specialists or the general physicians. WHO, for better or worse, has been trying to get the best talent around the world and they have been saying that a concept like essential drugs is perfectly valid. Essential drugs that can cope with 95% of the problems even in relatively sophisticated societies number around 200. But for the Third World villager and urban slum-dweller great miracles can be achieved with 50 well-chosen drugs. It was WHO's neutral role as an arbiter that led to the realisation that there is nothing shameful in speaking about essential drugs. Now the onus is back on the governments. Can they now get their experts together and enforce this concept?"

In the confrontation over the marketing of baby milk powder, Mahler believes "WHO has played a unique role by providing a neutral platform. What we achieved was not a miracle, but when you compare it with the situation ten years ago, it was remarkable that industry, non-government organisations, and member states from developing and developed countries, could arrive at this kind of consensus. It was certainly a very

Halfdan Mahler:

‘Medical education is such that it teaches the new professionals to love the highest technology and medical research’

unpleasant kind of confrontation. I was very concerned about WHO getting involved in it. But slowly we picked up the courage and hoped that it would not end in a disaster. And it didn't. Now member-states will have a code of conduct for marketing of infant formulae. This will be a model which they can adapt to their conditions.”

WHO has also had confrontations with the scientific community, which Mahler says “finds it very unpleasant when you speak about social relevance and social equity. But take these one million kids dying in Africa from tropical malaria. Somehow, it must be possible to mobilise enough social commitment among those scientists involved in health research to say that this cannot be tolerated when we have such fantastic scientific tools today. Well, scientists initially said we are prepared to do our little bit as long as it is marginal. Now through our diarrhoeal diseases, tropical diseases and human reproduction research programmes, we are dragging them. We have opened our doors to the scientists. I think the response has been very good and will be increasing in the future.”

But is providing a neutral platform and creating a consensus enough in these confrontations? Is WHO happy with the speed with which the essential drugs programme is being implemented, for instance? “No, certainly not,” says Mahler. “But then we have to ask ourselves whether WHO isn't becoming a little megalomaniac in this field of drugs. WHO now finds itself fighting the world at large. We are now moving straight into technology, production, patents, trademarks, the elements of a new international economic order in the widest possible sense. Is this WHO's role? I think we have set the scene, and other organisations like the UN Conference on Trade and Development, the UN Industrial Development Organisation, World Bank, etc, should now play the key role. If you

look at the drugs scenario, despite its imperfections, there is already a lot of courage, in espousing the essential drugs idea, courage by a number of developing countries now developing national drug policies, and courage by member-states in the Pacific region, for instance, who have got together under WHO auspices to decide on collective purchasing so that they can negotiate with drug suppliers much more strongly than in the past.

“But still I am not happy with the speed of the essential drugs programme but that is because I am not happy with myself. I don't seem to have the necessary social or economic ability to accelerate the process. And, therefore, I want to involve UNIDO, UNCTAD, etc into whatever I can do, and the drug industry itself, by asking it what can be done. I can give you an example. It was rather startling. We had a conference and the industry spokesman said that the production of vaccines and sera is so competitive that they were losing interest in it. What conclusion can you draw from that? When you want health for all and want to prevent six million children from dying from tuberculosis, whooping cough, diphtheria, measles and polio every year, then you need to vaccinate 100-120 million children every year. In order to get that you need a vaccine price that is low. But when the price is low, you can't get the products. So my conclusion is that we can no longer treat these vital, essential components of people's health as normal commodities in the market place. They may have to be taken out of the market place and other ways found to produce these essential drugs. But all of this obviously generates tremendous contradictions.”

But what about the contradictions inside the house? To what extent has the Mahler revolution filtered down within WHO itself? Mahler has several times told his staff that WHO should not be an academy of health sciences but a centre for managing health.

Mahler agrees that there is an internal contradiction. “It is difficult to take the plunge from doing things that you do well, to continue to do them well but with a very much sharper relationship with this overall target of health for all. The secretariat is asking, are we not throwing out the baby with the bath water? We had all these good technical things. Is the gap not too big between all these expectations of a social mission and our limited but well-done technical mission? This challenging target of health for all set by the member-states collectively is probably the only way of bringing the high priests on their toes — the high priests inside the secretariat and in the individual member-states.”

Could not WHO's technical reputation suffer in the process? Could it not find that it has compromised its technical reputation as well as failed to achieve its social goal? Mahler believes that the danger is there, but it does not inhibit him.

“Take the case of smallpox eradication

which was first decided on in 1957. The internal technicians in WHO — and don't forget I am one of them — claimed for ten years on technical grounds that the job could not be done. However, in 1968 we turned the argument around and said smallpox shall be eradicated and the political commitment shall be taken for granted. We worked backwards to see how our techniques and our management would allow this political commitment to manifest itself, and how our technologies could do the job. And we succeeded.”

“Most people analysing the contemporary world will say, forget about health for all. They will tell you that you will soon have a nuclear war in several of the developing countries. If you look at the world without a feeling for this imperative, historical necessity to change, then obviously you will generate a climate of gloom, and then be discouraged by it. Inside WHO, we could have gone on with basic health services, some tuberculosis, some malaria work. But now we have forced ourselves politically into interfacing with the collective aspirations of our member-states.

“I do not think that there is one person who can say that this change requires less of him technically. I think it requires infinitely more scientific imagination, in order to lift our technological thinking out of our cocoons in such a way that it relates more meaningfully to this broader social perspective. But I do not believe that in the process any of the conventional technical activities will be lost. In fact, the large majority will have become infinitely better within the next 5-10 years and more relevant to our social targets. In recent years, we have been generating the various research programmes, the expanded programme for immunisation, and planning for clean drinking water and sanitation, with the target of ‘clean water and sanitation for all by 1990’. All these programmes have highly explicit objectives. These objectives are key components of primary health care. The programmes are helping people somehow to identify with the components of the overall strategy. So now you have within WHO a progressive improvement, from a kind of technocratic alienation to begin with, to an identification with the major programmes that will be filling out the various major gaps in primary health care.”

WHO must become more responsive to the realities of the world, he says. “I have been asking member-states: do you really think that a technocracy like WHO should continue to exist? Either you believe that you can make WHO big enough to assume this brokerage role at the global, regional and country levels, or you don't. If you do, then we have to make a lot of agonising changes, and there will be no peace. But if and when the member-states realise that WHO cannot assume that larger mission, they should have the courage to say that we

couldn't make the organisation swing around to what we all believe should be done, so let's get rid of it. Let us not keep the system for some spurious political motive."

But Mahler is optimistic on several counts: "I think that we have to a large extent successfully called the North-South bluff in health. And having called it, it is beginning to hurt. I know many politicians in the Third World are very uncomfortable with the present situation in which the elite is eating up 80-90% of the resources. There is a genuine debate on health in the industrialised countries too, though to a lesser extent."

Given the "hysterical conservatism" that is rampant in the developed countries, Mahler is still not sure to what extent they are prepared to help the developing countries achieve the goal. But he argues the South "now has a much better chance of moving towards self-reliance in health. Now it can challenge the North by saying that to achieve our collective goal of health for all which we all have collectively decided, we will do 95-97% of the job ourselves. Will you not let us have that 2-3% of support that is essential for us to make the best of our 95-97%?"

And why should the developed world help? Because in the process it would only help itself. "Take the case of smallpox eradication. Ironically, it is the rich world that is making, according to a moderate estimate, a profit of about a billion dollars a year — savings in vaccine production, in treatment of complications, in surveillance mechanisms, in the tremendous waste of time involved in having to make vaccination compulsory. Now I should have thought it moderately reasonable on my part to say that half of the profits should go back to the developing countries. They did it really for the sake of the developed countries. Take Africa. Their form of smallpox was not very serious. They could live with that. If you have a million children dying from malaria, it is not the most important thing to eradicate smallpox. But because of its commitment to global solidarity, Africa had to eradicate smallpox. It just shows how inter-dependent the nations of the world are in health."

When developing countries undertake research into their own problems, even then the West benefits. "Take my own little experience in tuberculosis," says Mahler. "In the 1950s, when I went to work in India, we were exporting the classical European notion of TB sanatoria. India then had three million cases of TB and little money to diagnose, treat or immunise. Well, the government of India picked up the courage to do research itself, and indeed the consequence was that the chemotherapy research that came out of the Madras TB research centre became internationally the most important. The centre succeeded in standardising the procedure of diagnosis, and in developing the concept of

Medicine in two worlds: primary care in Africa, high technology in the North

intermittent home-based treatment. All of this research was clearly geared to India's absolutely incredible problem, and these were studies that would never have been done anywhere else in the world.

"Yet, ironically, the great beneficiaries of all this research were the rich countries. Hundreds of millions of dollars have been gained in the developed countries by making use of the Indian research. A European country I recently visited has been able to avoid constructing 3,000 beds for TB treatment because they now have the WHO expert committee's recommendations based on research done in India that home-based treatment is adequate. This was the effect in just one developed country."

But probably what the developed countries will gain most is knowledge about how to handle their own health problems by emulating the approaches being developed in the Third World — a kind of reverse transfer of technology.

"Global standards of health and well-being are declining: life expectancy, after reaching a peak, is now again decreasing; cancer rates are rising; cardiovascular diseases are rampant; drugs, alcohol, cigarettes and traffic accidents nowadays

kill more people than did all the epidemics together in earlier centuries; the aged are overwhelmed with diagnostic tools and abstruse technology, but their psychosocial and mental well-being is left largely unattended and uncared for.

"This uneasy feeling about today's medicine is widespread. As a consequence of the present high technological pitch of diagnostics and therapeutics, the very attempt to diagnose and treat one disease may produce another. As many as 20% of hospital admissions are reported to fall in this category in certain parts of the affluent world. Our world has become too accustomed to believe that with a little bit of resources and a little bit of knowledge any problem can be solved.

"I think that an appreciation of the South's real health problems will have a better chance to emerge once the North gets a feeling for the incredible irrationality that exists in its own health system. This will be an additional factor leading to the true global solidarity necessary to achieve health for all the world's peoples. If you look at our concepts about the transfer of science and technology, then I have no hesitation in saying that we really are out among the *avant-garde*."

CORRESPONDENCE

Two good reasons to reject the PWR

SIR, — Sir Alan Cottrell (*Nature*, 28 February, page 804) has put his finger on the principal weaknesses of the PWR — the two-phase coolant and the pressure vessel failure problem — either of which is a cause for doubting the wisdom of adopting this reactor for the UK. Taken together they are sufficient reason for abandoning the idea completely. One might wonder why our electricity authorities are so keen to get into the PWR business at all.

Power station construction engineers are perhaps the main pressure group. They have not performed well with the AGR for many reasons, including starting construction long before the design was ready, and trying to develop and prove major components as they went along. The resulting delays and cost increases are well known, and technical difficulties have been introduced that have caused poor operating records in the early life of finished stations. Now, with remarkable lack of introspection, the same engineers are identifying the culprit as the AGR itself; amongst other things, they say, it is too complicated mechanically and needs too much work on site. They regard PWR as the solution to their problems (or should we say shortcomings), for they have convinced themselves that it is much easier to build than the AGR. This is the dangerous sort of complacency that led to the Dungeness B fiasco, which was very nearly repeated with SGHWR.

The AGR is based on sound principles, uses good materials of construction, and has excellent safety and operating characteristics. This is a recipe for success but it does need first class detailed design and project engineering. So does any other type of reactor. It is no good running away from the gas-cooled reactors because it is thought, wrongly, that the PWR is an easier option. This simply wastes our limited technical resources to promote a reactor with some frankly undesirable properties. The better course is to recognise our failings, capitalise on experience and concentrate our best professional efforts on making AGR the successful UK thermal reactor that it can now be.

Yours faithfully,

Concentrating ethanol

SIR, — The amount of energy used in distilling off ethanol has not escaped attention to quite the extent that Taylor (*Nature*, 17 January, page 714) suggests, (see E. V. Anderson, *Chem. Engng News*, 31 July, 1978, page 8). In a simple still, nearly as much energy is discharged in the cooling water as is available from the ethanol. This waste of energy can be greatly diminished, at a price, by using multiple effect or vapour compression distillation units. Vapour compression is particularly attractive because ethanol could then be continuously removed from the fermentation mixture at low pressure so that its inhibiting action on yeast fermentation would be minimised.

There are various alternatives to distillation. The most interesting is the use of a semi-permeable membrane. Thomas Graham, in the paper (*Phil. Trans. Roy. Soc.* 151, 183, 1861) in which he introduced the word 'colloid',

mentions "the well-known bladder experiment of Sömmerring". He gives no reference, but explains that the permeability of bladder is selective and water evaporates from the outside so that more concentrated ethanol remains within. This may well have been a traditional technique in Europe.

Geoffrey Gorer (*Himalayan Village*, M. Joseph, 1938) says that beer is hung up in pieces of gut in Bhutan so as to make a more potent drink. Perhaps we still have something to learn from primitive technology.

Soviet biotechnology

SIR, — Recently there has been a number of comments in *Nature* about biotechnology. In the issue of 10 January, (page 123) there was an attempt to assess the world situation in which, for instance, Japan was quoted as a world leader in this field; we would not dispute this claim. However, that "most socialist countries . . . are somewhat secretive as to detail" is a slightly misleading conclusion.

Whilst we were preparing the Society for General Microbiology Symposium on Microbial Technology in 1979 it came to our attention that the Soviet Union and other communist bloc countries also were becoming increasingly active in biotechnology. In 1978, for example, President Brezhnev at the 25th Party Congress cited the microbiological industry as a key growth area in the Soviet economy, the aim during the current five-year plan being to develop microbiological industry four times faster than any other sector of industrial activities.

The degree of commitment to biotechnology in the USSR can be judged by reference to just one programme, namely single cell protein (SCP) production. In 1977 Academician N.M. Zhavoronkov announced that the production of fodder yeast from various internally available raw materials was being planned to make the USSR self-sufficient in protein feedstuffs for animals by 1990. The 1980 forecast for SCP production in the Soviet Union is of the order four million tons per annum, a figure that makes interesting comparison with the UK's largest programme, the ICI "Pruteen" project, which should come on stream this year and is expected to produce 50,000 tons per annum.

Sakharov's plight

SIR, — The recent action of the Soviet authorities against our distinguished colleague academician Andrei Sakharov provides another testimony about the increasing violations of human rights and civil freedoms in the USSR.

One can understand (though not agree with) the decree of the Presidium of the Supreme Soviet of the USSR depriving Professor Sakharov of his numerous decorations. For scientists, however, it is difficult to understand the meaning of the decision of the Council of Ministers of the USSR, by which all the state prizes Andrei Sakharov was awarded in the last 25 years, have been taken away from him. Is he supposed to pay back the substantial amount of money which accompanied each of these prizes? Does the Soviet government really think that its decree will make Sakharov's discoveries (like the physical

principles for fusion reactors) non-existent or even invalid? Or that Andrei Sakharov will, by the decree of Soviet government, cease to be the author of them? For the first time Soviet reality has surpassed Orwell's visions.

Internal exile to Gorky deprives Sakharov of one of the main rights and privileges of the members of Soviet Academy of Sciences to have the conditions for carrying on his scientific research. It is not clear yet, whether the Soviet Academy is going to propose the expulsion of Sakharov from its membership, but it should be made quite clear in advance that such a step would have most harmful consequences upon international collaboration and contacts in science.

Disposal of carcinogens

SIR, — The International Agency for Research on Cancer (IARC), with the support of the Office of Research Safety of the National Cancer Institute, has recently undertaken a programme of research on the disposal of laboratory wastes containing carcinogens, which will give specific instructions for destruction and disposal of the various carcinogenic wastes from laboratories.

We give here a brief résumé of a meeting of the working group responsible for establishing guidelines and priorities for the programme. We welcome comments, information related to similar work being carried out in other laboratories, and suggestions for active collaboration in the programme. As resources available for work of this nature tend to have a lower priority than original work on carcinogenicity, it is particularly essential that available knowledge is pooled.

In discussing a general strategy for control of carcinogenic waste, the working group:

- emphasised that experiments involving carcinogens should be designed in such a way as to minimize the quantities of hazardous material used;
- recognised that the scale of operations varied with different types of experiments;
- stressed that a waste treatment should yield for disposal products having minimum adverse biological or environmental effects;
- recommended that control techniques should, as far as possible, be carried out at the experimental site to minimize transportation, which may involve a public risk; and
- insisted that an experimental plan should contain the action to be taken in the event of a substance escaping from control in the course of an experiment.

A waste control strategy must take into account both the types of material for which appropriate treatment would be required, as well as their comparative importance in terms of risk of exposure during manipulation.

In discussing possible approaches to waste destruction, it was recognised that properly designed incineration techniques require careful attention to a number of variables, such as temperature of operations, air supply and feed rate. An alternative approach is to develop suitable chemical reactions which yield non-hazardous products.

From a list of carcinogens to be considered in a destruction programme, aflatoxins, nitrosamines and polycyclic aromatic hydrocarbons were selected as the immediate priorities for investigation. Alkylating agents, halogenated compounds, aromatic amines and hydrazines were also considered as high priorities.

Yours faithfully,

NEWS AND VIEWS

View of Venus from Moscow

from D.M. Hunten

In this issue of *Nature* appear two papers (pages 243 and 244) reporting results from the Venera 11 and 12 entry probes, which completed their missions in December 1978. Earlier that month, four Pioneer Venus (PV) probes had also entered the atmosphere, the bus which carried them made measurements of the upper atmosphere, and the Orbiter commenced a long series of measurements expected to continue at least through 1980.

The Soviet and American probes made many measurements in common, as well as several unique to each. The current reports are in the latter category, and are of particular interest in complementing the Pioneer data as published in the 23 February and 6 July (1979) issues of *Science*.

Water vapour

Water vapour, an extremely important molecule, is difficult to measure reliably in small quantities. The PV mass spectrometer has not reported any measurements of H_2O except those stemming from the cloud drop that lodged on its inlet tube. The vapours from its decomposition and evaporation left little doubt that the drop was concentrated H_2SO_4 solution, but made it impossible to determine the corresponding abundances in the free atmosphere. The gas chromatograph reported rather large (in the context of Venus) amounts of water vapour, 0.5% at 44 km, a few kilometres below the cloud base. Previous analysis of Venus' radio emission observed from Earth, had set an upper bound of 0.1%, which pertains to the

bottom 10-20 km. The paper by Moroz *et al.* (this issue, page 243) reports far smaller amounts however, using optical spectrographic techniques.

The principal investigator, V.I. Moroz, is a well-known planetary spectroscopist, and the experiment is elegant both in its power and its simplicity. It consists of a filter-wheel spectrophotometer covering the wavelength range 430-1,170 nm with the very modest resolution of 30 nm. Included in its coverage are several bands of H_2O , which can be measured with assurance that most, if not all, of the absorption takes place in the free atmosphere. A serious complication arises from the presence of an optical 'cavity' between the clouds and the ground; some of the light seen looking upward has made one or more round trips over this whole path. With many measurements during descent, the effect can be allowed for, and the height profile of H_2O obtained. The mixing ratio is reported to be 20 p.p.m. (parts per million) near the surface, rising to 200 p.p.m. in the clouds. An earlier experiment on the same principle, aboard Venera 9 and 10, gave similar results but with considerably less assurance. It is also reported that a gas chromatograph on Venera 12 gave an upper limit of 100 p.p.m. below 42 km.

I, as a spectroscopist, am strongly inclined to believe the low abundances. Needless to say, the PV experimenters, led by Vance Oyama, are concerned about the discrepancy and have worked hard to resolve it. They can find no problem with their experiment, and point out that the amount of H_2O they observed would require a large and improbable source of contamination. An ordinary cloud drop, for example, would not be enough. So far there is no reasonable explanation, but

most workers tend to favour the optical results.

Other data from the spectrophotometer bear on the structure and properties of the clouds, and on the possible presence of a number of trace gases. Considerable absorption in the blue is apparent and could be explained by the presence of S_2 , Cl_2 , Br_2 , or NO_2 at a hundredth of a p.p.m. or less (depending on the gas). Much larger quantities of sulphur, previously advocated, are clearly ruled out.

Lightning on Venus

Before the recent encounters with Venus and Jupiter, we had no evidence about the presence of lightning anywhere but on Earth. Voyager photographed what appear to be lightning flashes on the night side of Jupiter (*Nature* 280; 794; 1979), supplementing the earlier but less direct evidence from Venus. The new paper by Ksanfomali (this issue, page 244) reports the results from the sferics detectors on Venera 11 and 12. (Sferics, a contraction of 'atmospherics', are the electromagnetic impulses from lightning discharges, commonly heard on an AM radio receiver.) Abundant signals were recorded from both probes, and a periodic modulation on Venera 11 suggests that the antenna pattern was being rotated past a distant source. On the hypothesis that the individual strikes dissipate the same energy as on Earth, the 'storm' was located at a distance of some 1,500 km. This modulation is perhaps the strongest evidence that the signals were not merely due to electrical discharge from the probes themselves.

Additional support comes from an experiment on the PV Orbiter, whose purpose was to study the properties of the plasma at high altitudes. Normally the ionosphere totally reflects all low-

Donald M. Hunten is a Professor in the Department of Planetary Sciences at the University of Arizona, Tucson.

frequency radio waves, and sferics are not observed by satellites. But there are special circumstances where energy can propagate through in the so-called 'whistler mode'. These conditions, as measured by other instruments on the Orbiter, are thought to occur fairly frequently on the night side of Venus. When they do, the plasma-wave detector sees impulsive signals of a kind not normally encountered at orbital altitude. The instrument would need much better time resolution to obtain the length or shape of the pulses, but they are consistent with an origin from lightning and no other explanation has been suggested. Taken all together, the evidence for lightning on Venus is fairly convincing.

Ksanfomaliti also suggests that lightning could generate a mean nightside brightness 10^{-4} that of the day side. This source is put forward as an explanation of the 'ashen light', a phenomenon reported by many visual observers who see the whole disk faintly illuminated when the planet is in a crescent phase. It remains to be seen whether such suggestions and reports can be reconciled with the brightnesses observed from vehicles close to Venus.

The indications are that lightning is likely to occur in any substantial planetary atmosphere. Theories of electrification are faced with the need to explain its presence under a wide variety of circumstances and atmospheric compositions. □

Hammond found that progesterone secretion from granulosa cells *in vitro* taken from small immature pig follicles could be inhibited by prolactin. Short-term oestradiol treatment also suppressed progesterone secretion. However prolonged treatment with oestrogens (for 48 h) resulted in increased progesterone secretion and reversed the action of prolactin from inhibition to synergistic stimulation of progesterone. The authors conclude therefore that "oestrogens may regulate the divergent actions of prolactin in the mammalian ovary."

The basis of the oestrogen requirement for proliferation and maturation of granulosa cells is as yet unknown. Thus the change in response to prolactin seen in the present experiments may simply reflect the maturation of granulosa cells: prolactin will stimulate progesterone secretion from granulosa cells taken from large mature pig follicles. In this respect the effects of prolactin in the pig follicle may be different from those in the human where high levels of prolactin inhibit progesterone secretion from granulosa cells regardless of the stage of follicular development.

The importance of the direct inhibitory effects of high prolactin levels on steroidogenesis by granulosa cells in follicles before ovulation is emphasised by the fact that the rare cases of ovulation in hyperprolactinaemia, in particular that associated with lactation, is associated with an inadequate corpus luteum capable of secreting only limited amounts of progesterone (McNeilly, Howie & Houston, unpublished data). This suggests that prolactin-mediated inhibition of normal granulosa cell development before ovulation may explain the inadequacy of luteal function. This is supported by the observation that drug-induced hyperprolactinaemia in the luteal phase has only a slight effect on progesterone secretion from the developed corpus luteum whereas hyperprolactinaemia induced during the follicular phase results in the formation of an inadequate corpus luteum (Delvoye *et al.* *C. r. Seanc. hebdom. Acad. Sci. (Paris)* Ser D. **279**, 1463; 1974). McNatty (*Fertil. Steril.* **32**, 433; 1979) has provided more direct evidence in support of this. Raised levels of prolactin in plasma and ovarian follicular fluid were associated with a reduced number of granulosa cells and a marked reduction in intrafollicular steroidogenesis, not always apparent from the levels of circulating oestrogens.

Thus it seems that prolactin may have an important regulatory role in granulosa cell development within the follicle. Although present reports suggest that oestrogens may modulate the action of prolactin, the species difference in this action has yet to be resolved. The importance of understanding these mechanisms is apparent since hyperprolactinaemic blockade of steroidogenesis may in part explain the natural contraceptive effect of lactation in women and many other mammals. □

Paradoxical prolactin

from Alan S. McNeilly

LACTATION in many mammals is associated with suppression of ovulation as a result of the failure of ovarian follicles to develop to the appropriate stage. The widely varying suckling patterns in different societies (from very frequent short periods, for example in the !Kung peoples of the Kalahari, to infrequent longer periods of suckling) are all associated with suppression of normal gonadotropin secretion and of ovarian activity, and with raised basal levels of prolactin which increase further in response to the suckling stimulus (see McNeilly *Br. Med. Bull.* **35**, 151; 1979). As ovarian activity normally resumes once suckling ceases, either the suckling stimulus itself and/or the raised levels of prolactin may be responsible for the suppression of gonadotropin secretion and the consequent failure of normal follicular development.

The best evidence that the prolactin level itself may be responsible for ovulatory inhibition comes from cases of pathological hyperprolactinaemia which is the apparent cause of 20% of secondary amenorrhoeas. Unlike lactation, the raised prolactin levels in this condition may be due to an alteration in hypothalamic catecholamine turnover. The way in which prolactin itself may play a part has received scant attention; it may act on the hypothalamic-pituitary axis to suppress gonadotropin secretion, or may act directly on the ovary to suppress follicular development.

Evidence that prolactin is implicated in normal follicle development has been obtained from studies of progesterone

secretion from human granulosa cells *in vitro* (McNatty, Sawers & McNeilly *Nature* **250**, 653; 1974). Levels of prolactin equivalent to those seen during the normal menstrual cycle were essential to maintain LH-stimulated progesterone secretion. In contrast, high levels of prolactin equivalent to those present in lactation and pathological hyperprolactinaemia inhibited progesterone secretion, an inhibition which could not be overcome by the addition of gonadotropins (LH or FSH). A similar situation was apparent in the mouse where follicular progesterone secretion *in vitro* was also inhibited by high levels of prolactin (McNatty, Neal & Baker *J. Reprod. Fertil.* **37**, 155; 1976).

But how prolactin can have both an obligatory permissive role in progesterone secretion and an inhibitory effect remains unexplained. Studies by Veldhuis and Hammond (this issue of *Nature*, page 262) go some way to resolving this dilemma. Using short term *in vitro* studies of progesterone secretion from porcine granulosa cells they found that oestradiol 17β seems to modify the action of prolactin.

Previous studies suggest that development from a primordial to a Graafian (preovulatory) follicle is initially under the control of FSH and oestradiol. LH stimulates oestradiol and androgen secretion from the thecal layer of cells surrounding the developing follicle; FSH stimulates aromatisation of these androgens to oestrogens by the granulosa cells within the developing follicle. Both FSH and oestradiol are required for the proliferation of granulosa cells and antrum formation within the developing follicle and induce an increase in LH receptors on these granulosa cells. Prolactin is detectable within follicular fluid of all follicles and receptors have been detected on granulosa cells. Veldhuis and

Alan McNeilly is a Research Scientist at the MRC Unit of Reproductive Biology, Edinburgh.

Between the galaxies

from M.G. Edmunds

WHO could ask for a better probe of the material between the galaxies than that provided by quasars? Situated at a range of distances, some very great, the quasars give off plenty of radiation to allow the absorption spectrum of the intervening gas to be observed on Earth. The use on the largest telescopes of very sensitive light detectors capable of working with high wavelength resolution has led over the past few years to rather good data on the absorption spectra of several quasars. Particularly successful has been a detector developed at University College, London. Data on six quasars obtained with this instrument have been used to deduce the existence and properties of clouds of intergalactic material (Sargent, Young, Boksenberg & Tytler *Astrophys. J. Suppl. Ser.*, **42**, 41; 1980). These gas clouds are thought to be pure remnants from the initial 'Big-Bang'.

A formidable array of statistical tests on the spectra identified two main sources of absorption. The authors concentrate their attention on the Lyman- α line of hydrogen which normally appears in the ultraviolet at 1,216 Å, but the expansion of the Universe redshifts this line into the optical region as observed from Earth provided the absorber is far enough away. The Lyman- α emission (and absorption) intrinsic to the quasar and its surroundings are of course at the highest redshift in the spectrum, but many other absorptions almost certainly attributable to hydrogen appear at redshifts smaller than that of the quasar's Lyman- α . In interpreting the origin of these lines, the observed family of lines arising from three-times ionised carbon (CIV) is important. Of the two distinct types of absorbing region which seem to be present, the first kind gives rise to these CIV lines and simply represents the outer regions of galaxies through which the light from the quasar passes on its way to us. There is good evidence that the outer parts of galaxies do contain sufficient gas at the right excitation state to provide the absorption, as the same CIV line is seen in the outer halo of our own Galaxy when looking at the ultraviolet spectra of sources nearby, but outside, our own system (for example the International Ultraviolet Explorer Satellite observations of sources in the Magellanic Clouds reported by Savage and de Boer *Astrophys. J. Lett.* **230**, L77; 1979).

But the other type of absorbing region which gives rise to Lyman- α but no CIV is new, and is suggested to represent true intergalactic clouds. The physical parameters of these clouds are inevitably uncertain but the proposed sizes are 2×10^7

solar masses and a typical linear dimension of 30 kpc. This extent is about the same as a medium-sized galaxy, but the density of the cloud is very much smaller, as that of a galactic mass will be more than 10^{11} solar masses. The gas in the clouds seems to contain no (or very few) heavy elements — that is, nothing more complex than helium, as no absorption lines of heavy elements are seen at the wavelengths expected on the basis of the redshifts of the hydrogen lines. This implies that the gas is a pure remnant from the Big-Bang initial synthesis which leads to production of hydrogen and helium, but very little else. This contrasts with the gas in galaxies (and their halos) which has been contaminated with heavy elements produced by nuclear reactions in stars and their supernovae explosions. From the relative distances of the clouds as implied by their redshifts, the clouds are not clustered together in space in the way that galaxies are. This is good evidence that they represent genuine intergalactic clouds, and are not associated in any way with existing galaxies.

The discovery of a very primitive kind of object in the Universe is an interesting one, but it must be pointed out that the clouds may have comparatively little influence over the evolution of the Universe as a whole. Their number per unit volume of space at present is only about five per cubic megaparsec, fewer than the observed galaxies and very much less significant in terms of mass. Thus these new objects certainly do not supply sufficient mass to close the Universe and make it eventually re-collapse on itself — a role often proposed for intergalactic material.

Sargent *et al.*'s analysis of the thermal state of the cloud gas implies that the clouds are too hot to be bound by their self-gravitation, and must be confined by an even hotter tenuous intergalactic gas. But it is significant that such a gas could still not be hot enough to provide enough X-ray emission to explain the diffuse background of X rays observed in space. (The initial results from the Einstein observatory imply that much of this background may anyway be due to the quasars themselves). The allowed cloud parameters are apparently rather tightly constrained — in these physical conditions a rather bigger or smaller mass than is suggested gives theoretical estimates that imply they would either collapse or evaporate. It is perhaps surprising that such fragile clouds have managed to survive to the present day — presumably they represent a small fraction of clouds of a whole range of sizes which formed early on in the evolution of the Universe. The other clouds either collapsed (and perhaps combined) to give galaxies and quasars, or else dispersed to become the diffuse intergalactic medium.

Can we see any of these primitive clouds near our own Galaxy? The International Ultraviolet Explorer Satellite provides an opportunity to look at the brightest quasar 3C 273, but as yet no conclusive evidence of suitable Lyman- α absorption has been reported, although the CIV absorbing gas of our own galactic halo is clearly visible. But the number density of the clouds would predict only three clouds in the line of sight to 3C 273 — so even a complete failure to detect anything would not be too surprising on statistical grounds.

Undoubtedly this study goes a long way to demonstrating that a large fraction of absorption lines in quasar spectra may be satisfactorily explained as not being intrinsic to the quasars themselves, but due to the outer parts of galaxies and to clouds in the intergalactic medium. Just what fraction of the remaining absorption lines can be attributed to gas driven out of the quasars remains to be seen. □

Electrically conducting polymers

from Paul Calvert

FOR some time people have been looking for polymers with metallic conductivity or with superconductivity. Sulphur nitride was found in 1975 to be a superconductor at low temperatures and sparked a great deal of research which now seems to have mainly fizzled out. At the moment polyacetylene seems to have potential as a metallic conductor and is the subject of much interest.

For a material to be conducting there must be a supply of charge carriers, electrons or 'holes', and an easy, high mobility path for them to follow through the material. Thus one class of polymeric conductors consists of conjugated chains, with alternating single and double bonds, such that the pi-bonding orbitals overlap to form a path along the chain. Examples of this are sulphur nitride $(-S=N-)_x$ and polyacetylene $(-CH=CH-)_x$. Alternatively, stacked planar aromatic molecules can provide an easy conduction path perpendicular to the molecular plane as in graphite. Hence the interest which developed at one time in the conductivity properties of DNA, where the stacking of the base pairs suggested that the molecule could be a 'one-dimensional' conductor.

Acetylene normally polymerises to a grey, insoluble, infusible powder with all the properties of brick dust, except price. However in 1974 T. Ito, H. Shirakawa and S. Ikeda at Tokyo Institute of Technology (*J. Polym. Sci. Chem.* **12**, 11; 1974) produced thin films by exposing acetylene gas to concentrated solutions of Ziegler

M.G. Edmunds is in the Department of Astronomy and Applied Mathematics, University College, Cardiff.

Paul Calvert is a lecturer in the School of Molecular Sciences, University of Sussex.

catalysts. Films formed on the liquid surface consisting of *cis*-polyacetylene at low polymerisation temperatures and *trans*-polyacetylene at high temperatures. Electron microscopy (*Nature* **282**, 286; 1979) shows these films to be mats of fibres of about 20 nm diameter and low density, 0.4 g cm^{-3} compared with a theoretical value of 1.2 g cm^{-3} .

Shirakawa in conjunction with A.G. McDiarmid and coworkers at the University of Pennsylvania measured the electrical properties of these films (*Phys. Rev. Lett.* **39**, 1098; 1977; *Chem. Commun.* 578; 1977). The conductivity of the *trans* polymer is in the range 10^{-4} – $10^{-3} \text{ ohm}^{-1} \text{ cm}^{-1}$ which makes it a semiconductor and not particularly interesting. The *cis* polymer has a conductivity of about $10^{-9} \text{ ohm}^{-1} \text{ cm}^{-1}$. However on exposure to iodine vapour to dope the polymer with 68% iodine ($\text{CHI}_{0.22}$) \times the conductivity of the *trans* polymer increased to $40 \text{ ohm}^{-1} \text{ cm}^{-1}$. At 1% iodine the polymer took on a silvery metallic appearance and went through an insulator-to-metal transition. The *cis*-polyacetylene reached conductivities of 10^2 – $10^3 \text{ ohm}^{-1} \text{ cm}^{-1}$, 11 orders of magnitude above the pure polymer values.

A range of dopants can be used (*J. Am. Chem. Soc.* **100**, 1013; 1978) and, in the same way as in semiconductors, both p and n-type materials can be produced such that a simple diode is made. Recently experimenters have used arsenic pentafluoride rather than iodine as it is less easily lost by evaporation. If the films are stretched to three times their original length the conductivity as doped becomes anisotropic, 2,000–3,000 $\text{ohm}^{-1} \text{ cm}^{-1}$ parallel to the stretch direction and 100–200 $\text{ohm}^{-1} \text{ cm}^{-1}$ perpendicular. Because the film resembles a knitted structure it is not clear to what extent this reflects changes in inter-fibre contacts and to what extent it is due to internal structural changes. F.E. Karasz, J.C.W. Chien and coworkers at the University of Massachusetts in cooperation with McDiarmid have been looking at the effect of varying polymerisation conditions and have found increases in conductivity if films are prepared at low densities and then pressed (*J. Polym. Sci. Lett.* **17**, 779; 1979).

A wide variety of spectroscopic techniques has been applied to the doped films but there is still much to learn. R.H. Baughman and S.L. Hsu of Allied Chemical report finding I_3^- and I_5^- in iodine-doped films (*J. Polym. Sci. Lett.* **17**, 185; 1979). T.C. Clark and G.B. Street of IBM say that oxidation always occurs to produce ionised chains with the counter-ions intercalated between the chains. When the charge density is sufficiently high the charges delocalise along the chain and the material becomes conducting (Preprints, A.C.S. Honolulu Meeting, 1979; *Chem. Commun.* 1066; 1978).

A number of related systems have been studied. Poly(*p*-phenylene) $(\text{—}\text{C}_6\text{H}_4\text{—})_x$ has a

Role of hydrogen in amorphous silicon

from P.G. Le Comber

SINCE 1975, when it was first demonstrated that it was possible to control the electrical properties of amorphous silicon (a-Si) by substitutional doping (see Spear & LeComber *Phil. Mag.* **33**, 935; 1976), there has been a tremendous increase in the number of laboratories throughout the world working on both the fundamental properties of this material and its possible applications in solar cells, low-cost p-n junction diodes, thin film transistors, vidicon camera tubes and in electro-photography. With the recent announcement by the Sanyo Company of Japan that it is manufacturing calculators, watches and clocks powered by a-Si solar cells, we can expect this effort to be intensified still further.

The particular form of a-Si which has aroused all this interest is prepared as a thin film about $1 \mu\text{m}$ thick by the decomposition of silane (SiH_4) gas in an r.f. glow discharge. It is now known that this material contains upwards of a few percent of hydrogen and in fact many workers (but not all) believe that these relatively large concentrations are essential for the good electronic properties of these films. In view of the potential of a-Si in a wide variety of applications it is clearly important to understand the role of hydrogen in producing and possibly limiting its desirable properties.

In a recent issue of *Physical Review Letters* (**44**, 43; 1980), D.C. Allan and J.D. Joannopoulos, at the Massachusetts Institute of Technology, have calculated the electronic states and total energies of the various configurations in which H atoms could be bonded into the amorphous silicon network. Allan and

Joannopoulos claim that there are limitations in previous publications on this subject and conclude that strongly interacting nearest-neighbour silicon monohydrides have an important role, particularly in the interpretation of the photoemission spectra. They also find that the energy gap increases with increasing H content, in agreement with published optical data. Their results show that the valence band recedes rapidly with increasing H content but that the conduction band remains essentially unchanged. Possibly their most interesting conclusion, however, concerns the large ϵ_y peak in the density of localised gap states that is observed in field effect and other experiments. Since it is believed that it is these ϵ_y states that at present limit the performance of a-Si solar cells, by understanding the nature of these states one might be able to reduce their numbers. Allan and Joannopoulos suggest that local fluctuations in the hydrogen content can create localised states near the valence band edge and that these could be the origin of the ϵ_y states.

It would be ironic if hydrogen, thought by many to be essentially only a positive factor in producing the good electronic properties of a-Si, turns out to be responsible through these fluctuations for limiting the performance of a-Si solar cells! This suggestion cannot be the whole story, however, since a-Si produced by thermal evaporation contains essentially no hydrogen and has an even larger number of states around ϵ_y than the films produced from silane. Nevertheless many laboratories will be interested in seeing if this suggestion by Allan and Joannopoulos provides, at the least, some clue to how to decrease the number of these states and thereby improve the efficiency of a-Si solar cells.

P.G. Le Comber is at the Carnegie Laboratory of Physics, Dundee University.

conductivity of $10^{-14} \text{ ohm}^{-1} \text{ cm}^{-1}$ which rises to $100 \text{ ohm}^{-1} \text{ cm}^{-1}$ with arsenic pentafluoride. This polymer is a very stable powder (*J. chem. Phys.* **71**, 1506; 1979). Poly(vinylphenylene) $(\text{—CH=CH—C}_6\text{H}_4\text{—})_x$ has a conductivity of $10^{-10} \text{ ohm}^{-1} \text{ cm}^{-1}$ rising to $3 \text{ ohm}^{-1} \text{ cm}^{-1}$ at 57% arsenic pentafluoride. This material has a degree of polymerisation of only eight, barely a polymer at all (*Polymer* **20**, 1441; 1979). Polydiacetylenes $(\text{—CR=C=C=CR—})_x$ are of interest in that the polymers can be prepared as large single crystals by solid state polymerisation of monomer crystals where the monomers are already aligned in the right way for chain formation. Despite the chains being continuous through the crystals and their metallic appearance they

are not conductive as apparently they have no charge carriers (*J. Polym. Sci. Phys.* **14**, 2037; 1976).

Simple models suggest that in long conjugated chains with all the bond lengths equal, electrons should be thermally excited into the conduction band at room temperature. This does not happen, apparently because all the bond lengths are not equal (due to the Jahn-Teller effect, for the cognoscenti) and because internal rotation about the bonds interrupts the conjugation. In addition to understanding charge mobility within the chains one needs to know how the charges transfer from one chain to another, which must partly be a function of chain length. Unfortunately this is all but unmeasurable since the

polymer is insoluble.

Polyacetylene is a tractable material because it can be produced as films; there is no prospect of further melt or solution processing. It is possible that acetylene might be induced to polymerise as a single filament in the same way as a silkworm produces silk, also infusible and insoluble. Alternatively films could be rolled up to form wires but this would hardly be cheap. More probable is that acetylene could be polymerised directly onto the surface of integrated circuits to provide controllable resistance elements. Perhaps the most intriguing aspect of this work is that it requires cooperation between theoretical chemists, physicists, polymer chemists and engineers. Communication may be difficult but the number of journals in which it can be published is immense. □

Modern refuse and ancient behaviour

from Mark Maltby

THE connection between a caribou hunting group in Alaska, Hottentot occupational debris, the contents of trash cans in Tucson, Arizona and animal bones recovered from prehistoric archaeological sites may seem tenuous but they all come under the umbrella of ethnoarchaeology, a discipline that has assumed increasing importance in archaeological studies over the past 15 years.

Ethnoarchaeology attempts to interpret the behaviour of a society by means of its material culture. By trying to understand the relationship between these in present-day societies it may be possible to reconstruct the behaviour patterns of prehistoric groups by studying their archaeological remains. There is nothing new about archaeologists turning to the ethnographic record for inspiration but most anthropological fieldwork on the other hand, has tended in the past not to record in detail the artefacts, refuse, house and settlement plans, which often provide the only source of evidence for archaeologists. Consequently many American archaeologists took it on themselves to collect data more relevant to their own studies. There is now a rapidly increasing literature on ethnoarchaeological case studies from all over the world, mostly on hunter-gatherers but also on nomadic pastoralists, sedentary farming groups and even industrial societies. Analyses of the production, form, variability, use and discard of artefacts such as stone tools and pottery have been made. Various aspects of subsistence activities, the internal

organisation of settlements, the correlation between social status and material culture and the regional patterning of settlement sites and other activity areas have been studied. Several recent studies have concentrated on food refuse, animal bones in particular, and these can be used as examples of the scope of ethnoarchaeology and its potential for helping to understand the past.

Most animal bones recovered from archaeological sites were discarded as refuse but surprisingly little is known about the processes that determined the observable patterns of bone fragments and other refuse in excavated deposits. The need for a greater awareness of such processes prompted several studies of modern rubbish disposal. Perhaps the most ambitious of these — and in many respects the most unusual — has been the Garbage Project of the University of Arizona (Rathje in *Explorations in Ethnoarchaeology* (ed. Gould) 46, University of Mexico Press, Albuquerque, 1978). In this project rubbish from several hundred households in Tucson, southern Arizona was systematically sorted. The garbage has been put into more than 150 categories representing food, drink, drugs and so on and further relevant information about each item has been noted. For example, the weight, type, cost and brand of discarded food or its containers are all recorded. The analysis of this data is incomplete but the potential of such a survey for elucidating the social patterns underlying refuse disposal in a contemporary urban community is of value to archaeologists as well as social scientists.

Other ethnoarchaeological work has examined in detail the processes of fragmentation and preservation of animal bone. One of the earliest examples was that of Brain (*Scientific Papers of the Namib Desert Research Station* 39, 13; 1969), who examined discarded goat bones from recently abandoned Hottentot villages and was able to show that certain bone fragments had survived better than others and that preservation was linked to the density of the bone and the age of the animal to which it belonged. For example, sturdy fragments such as the distal portion of the humerus survived better than the more fragile proximal portion of the same bone. He used these data to refute Dart's claim (*Transvaal Mus. Mem.* 10; 1957) that the animal bones associated with australopithecine remains at Makapansgat, South Africa, had been manufactured as tools. Brain showed that the uneven representation of these bones was more probably due to differential preservation of their skeletal parts and not to any 'hominid' behaviour. Recently a more elaborate examination of the Makapansgat data has supported Brain's findings (Binford & Bertram in *For Theory Building in Archaeology* (ed. Binford) 77, Academic Press, New York, 1977). The problems of differential preservation have often been

ignored by archaeozoologists and it is only through these and similar studies that advances have been made in our knowledge of the preservation of archaeological bone samples.

The most detailed ethnoarchaeological case study on animal bones published has been carried out on the Nunamiut Eskimo in north Alaska (Binford, *Nunamiut Ethnoarchaeology*, Academic Press, New York, 1978). The Nunamiut rely principally on hunting caribou and Dall sheep for their food. Caribou are particularly important, providing the Nunamiut not only with most of their meat but also skins, marrow and bone grease. Most of the caribou are hunted during their spring and autumn migrations through the area inhabited by the Nunamiut. After a successful kill, the complete carcass may be transported to the village or skinned and more or less dismembered at the kill site and cached in the snow to be collected and possibly butchered further at a later date. Sometimes parts of the carcass may be abandoned at the kill site and never brought to the village. Some meat is required for immediate consumption in the village but most is stored either by freezing in cellars dug into the ice or by drying on racks. Further butchery may take place then and later during cooking. Certain bones are also smashed up to manufacture bone grease; others are broken to obtain marrow and some are thrown to the dogs.

All this transforms the skeleton of each caribou into a large number of distinct bone fragments scattered over several sites. The variability in the treatment of different carcasses is also reflected in the types of bone fragments deposited on the kill sites, hunters' camps and resident settlements. By combining his observations on Nunamiut behaviour with calculations of the value of the different bones for meat, marrow and grease and their general utility, Binford was able to construct models that could predict the types of bone fragments deposited at the different sites and examine the variability caused by the complex interactions of logistic, storage, mobility, seasonal and social strategies of the Nunamiut.

How can this and other ethnoarchaeological studies be applied to archaeological problems? If nothing else, they have demonstrated the potential complexity of animal bone assemblages — a complexity that has not been appreciated by most archaeozoologists and many statements that have been made about the proportion of different species represented, the relative abundance of their different skeletal elements, the kill patterns of the animals exploited and other aspects of archaeological data must now be viewed with suspicion. Ethnoarchaeological studies are, however, of most value if their information can be used constructively and Binford, for example, has claimed that some of the hypotheses generated and tested on the Nunamiut

J.M. Maltby is in the Department of Archaeology, University of Southampton.

bone assemblages can be applied to most archaeological samples. It is now necessary for archaeozoologists to adapt such hypotheses to their data. If such

adaptations are successful, the depth and range of information obtained from archaeological animal bones will have been greatly increased. □

Compartments, 'switches', 'programs' and vertebrate development

from Jonathan Cooke

It is now well established that in insect development small groups of founder cells are set aside in a hierarchically arranged series of geographical partitioning events such that each group is subsequently solely responsible for the construction of a defined piece of the epidermal body pattern. These pattern pieces, each the product of such a 'polyclonal compartment' set up in the embryo, need not correspond to morphological units as recognised by an anatomist. They are however identical and similarly positioned with respect to each other in each individual. This finding has formed an exciting link between the study of positional information (Wolpert *J. theoret. Biol.* **25**, 1; 1969) that is, the control of cells' activities according to their relative positions within the embryo during morphogenesis, and the study of possible mechanisms for progressive restriction of cells' potentialities during early development (Crick & Lawrence *Science* **189**, 340; 1975; Morata & Lawrence *Nature* **265**, 211; 1977).

There has naturally been speculation that what has been revealed in insects, with their intricate and distinctive body surface and their suitability for the somatic genetic marking of cell clones during development, is in fact general to many types of embryo. Methods now exist for marking clones over long developmental periods by injecting

Jonathan Cooke is at the National Institute for Medical Research, Mill Hill, London.

the founder cells with 'heritable' substances (Weisblat *et al. Science* **200**, 295; 1978; Jacobson & Hirose *Science* **202**, 637; 1978), and first attempts to probe for compartmentation in vertebrates have been directed at brain development. Here, a complex and exact anatomy is finally produced and there is little reason to suppose that populations of cell bodies intermingle on a large enough scale, at late stages, to obscure any earlier geographical organisation. The idea of a sequential, hierarchical series of events channelling the fates of cells early in development is a comprehensible and attractive one. What are the chances of being able to detect compartmentation in the vertebrate brain rudiment if this exists — or, more fundamentally, what meaning could the concept of polyclonal compartments have there?

Regulative embryos such as those of vertebrates are those in which the body pattern progressively becomes determined within a numerically expanding, sheet-like population of cells, and not those where lineal descent seems to define cells' fates from the outset as in the nematode worm or the leech. In one trivial sense all regulative embryos ultimately exhibit a compartmentation of the founder cells for each element of their bodies during undisturbed development. But vertebrate embryogenesis contrasts rather sharply with that of insects in the timing of the restriction process relative to the onset of overt

differentiation.

In the insect work, the dramatic outcome of clonal analysis (the exploration of development by marking all the epidermal cells coming from single founder cells picked out at particular times) has been the revelation that precise restrictions occur long before overt differences become apparent among the cellular descendants. The restrictions do not apply to which histological structures those descendants can differentiate into, but to which region of the body's pattern they can participate in constructing. Very many cell generations then intervene, during which the commitment is only expressed in subtle ways such as growth rates, or the lack of intermingling that actually preserves the integrity of the compartments. It is precisely the failure of the undifferentiated cells to invade alien pattern regions that lends the compartment concept its interest and meaning.

In vertebrate embryos however, especially in the primordial nervous system, there is a wealth of evidence that commitment to pattern construction on the part of small cell groups occurs relatively late in the cell lineage, when cell number is high, and predates hardly at all the onset of morphogenesis and the first stages of histological differentiation (for example, C.-O. Jacobson *Zool. Bidr. Uppsala*, **36**, 73, 1964; Chung & Cooke *Proc. Roy. Soc. B.* **201**, 335; 1978). Certain very early events, such as the separation of the embryo from its supporting structures in mammals, are exceptions to this. It is true that the decision by a population of cells within the amphibian ectoderm to form nervous system rather than epidermis occurs somewhat earlier than does regionalisation for brain structures within that committed population. But even the former decision is certainly delayed until the embryo contains more than 10,000 cells, and the ectodermal cells concerned seem on average to be in their 15th division cycle since fertilisation (Suzuki & Ikeda,

100 years ago

Who are the Irish? By James Bonwick, F.R.G.S. (London: David Bogue, 1880.) This little work is issued as the first of a series on "Our Nationalities," to be followed by three others on the Scotch, Welsh, and English. It does not appear from the prospectus whether the rest of the series is to be entrusted to Mr. Bonwick; but if they are it is to be hoped that he will qualify himself for the task by a preliminary study of at least the first principles of ethnology. The present volume, with all its good intentions and praiseworthy industry, must be regarded as a hopeless failure, owing entirely to the neglect of this necessary precaution. For many years ethnology, anthropology, and philology were subjects

which anyone seemed competent to deal with, who had got hold of a few lists of words in some obscure African or Polynesian dialects (the obscurer the better), or who had desecrated a sufficient number of ancient barrows, or posed to admiring circles under the shadow of some Druid's altar in Cornwall or Brittany. But those halcyon days of the amateur ethnologist are no more, though the writer, unfortunately, seems scarcely alive to the fact.

The following epigram on Dr. Siemens's recent paper has been sent us as by "a well-known scientific man". It is entitled Electric Chlorophyll:—

"Quis veterum vidit plantas sine sole virentes
Germinat en semen Siementis lumine claro."

It appears that the Berlin Municipal Corporation has granted to Dr. W. Siemens the concession of one electrical railway which will connect Wedding-Platz with Belle Alliance-Platz. The rails will be supported by

iron columns, which will not be an obstruction for the circulation of carriages and passengers in the streets. There will be no intermediate station between the two termini.

A deplorable accident has taken place at the Grenoble Lycée. The professor of chemistry was lecturing on salts of mercury, and had by his side a glass full of a mercurial solution. In a moment of distraction he emptied it, believing he was drinking a glass of *eau sucrée*. The unfortunate lecturer died almost immediately.

Mercury was seen at Paris on May 10 and 11 with the naked eye, owing to the transparency of the atmosphere and the great elongation of the planet. It had the brightness of a 1st class star, and was of a yellowish colour. The observation was made by M.M. Henry brothers, at the Paris Observatory.

Etna is again tranquil, its summit is once more covered with snow, and an ascent is contemplated, with a view to examine the alterations caused in the crater by the recent eruptions.

From *Nature*, **21**, 18 March 1880, 473-4; 1880.

Dev., Growth Differ. **21**, 175; 1979). The placement in cellular terms of the boundary between future brain and epidermis may be altered by grafting (for example Spemann & Mangold *Arch. Mikr. Anat. u. Entwmech.* **100**, 599; 1924) or by artificial imposition of physiological gradients up to this time, so that a recent claim that seven true compartments within brain structure are established within the 512-cell stage amphibian, besides being unsupported by the data produced (M. Jacobson *Trends in Neurosciences* **3**, 3; 1980), is incomprehensible and at odds with all other understanding.

There is no reason to believe that vertebrate groups other than amphibians are any more precipitate in marking out their brain plans. But most important, the means for a temporal analysis of the logic of cellular commitment, when it does take place, are denied us in these animals. This is because transition from pluripotency to quite detailed commitment within small pieces of neural tissue proceeds very rapidly in relation to the cell cycle. Cell number scarcely doubles in the neural plate and tube during the essential establishment of the brain's pattern. Marking clones will thus be of no avail in finding out whether in fact a telescoped version of the binary, sequential decision-tree that has so fascinated the *Drosophilologists*, also occurs among the cells of frog, chick and mammal embryos.

Closely associated in the insect literature with the idea of compartments is the concept of the 'selector gene'. This is based on the existence of a class of mutants called *homoeotic*, in each of which the cell populations that should belong to a particular set of the compartments instead show a tendency to construct, and thus duplicate, pattern regions proper to other compartments. Thus in one case, cells in the posterior of the anterior/posterior pairs of compartments that construct the wings (and also the obviously homologous 'halter' structures of the succeeding body segment), show a pronounced tendency to duplicate instead the structures proper to the anterior compartments, while in another case, antennal structures tend to be replaced by the leg pattern. Homoeotic mutations are now widely assumed to be in genetic units — the selector genes — whose wild-type function is literally turned on as a positive switch to define and maintain membership in one of the two compartments segregated by each restriction event at particular levels in a hierarchical sequence or 'program' (Garcia-Bellido *Am. Zool.* **17**, 613; 1977). Pairs of compartments are generated in parallel sequences from previously established ones, so that membership of each final compartment would be defined, simply and combinatorially, by the states of the set of on-off switches represented by the selector genes.

Again the idea, with its attendant image of the 'computability' of development, is

at present an attractive one. There is little doubt that the phenomena of polyclonal compartmentation and of homoeosis have revealed some sort of logical and combinatorial structure for restrictions on the potentialities of groups of cells during development. But I feel the selector gene model to be more an example of what Stent (*Trends in Neurosciences* **3**, 49; 1980) has termed the ideological component of the molecular genetic viewpoint, than anything logically required by the data. Shouldn't we do well at this stage to be flexible, rather than succumb to the current tendency for each aspect or event in an organism's life that attracts our interest promptly to become the express responsibility of a gene? Parallel manifestations of this incipient social disease in psychiatry and criminology need no comment, but they may also be seen in contemporary evolution theory (for example Dawkins *The Selfish Gene*, Oxford University Press, 1976; for a critique of the syndrome see Gould & Lewontin *Proc. Roy. Soc. B.* **205**, 581, 1979).

It was the great success of molecular biology to reveal that conservation and readout of the information that specifies proteins, and at least in prokaryotic cells, control of that readout, resembles in form the programs we design to retrieve and use information. Ideology only creeps into our view of development when it is supposed, without evidence, that the reliability and constancy of the phenomena seen there reflect an extension of the same sort of programming that controls the biosynthesis of the basic building blocks and signals. The complex and repeatable sequence of readout from the genetic library that accompanies development does not allow us to conclude that the process is actually being driven along by a digital program embodied in individual genes as molecular switches.

No experimental results yet require that any episode in the setting up of the body plan of any animal is literally the responsibility of a particular piece of DNA. The *bithorax* series of mutations in *Drosophila* (Lewis *Nature* **276**, 565; 1978) all occur in one short stretch of chromosome in a spatial order that could reflect the series of homoeotic transformations they cause between the compartments underlying the segmental plan of the insect. Here we have a hint that organisation of a stretch of genomic information may directly reflect the organisation of development, but specific selector genes need not be invoked as the targets for all or even most homoeotic mutations. Cells seem to be systems with a few stable end-states or pathways of development and a defined sequence of possible transformations between these, whether driven systematically or by chance perturbations (see Hadorn in *Major Problems in Developmental Biology* **85**, Academic Press, New York, 1967, for

other relevant phenomena in *Drosophila* cells).

Waddington (*SEB Symp.* **2**, 145; 1948) and Kauffman (*J. theoret. Biol.* **22**, 437; 1969), among others, have discussed how these observed properties might emerge at levels far removed from single genes as switches. The genome will surely contain many targets for mutations which modify various properties of all the developing cells (such as membrane transport, division rate or responses of control mechanisms to small molecules) in ways that are limiting only to their entry into certain of the available epigenetic states (that is, compartment designations). We might then expect these less available states or designations to be replaced on a systematic basis by alternative ones. Until direct molecular knowledge is at hand that justifies us in replacing views like those outlined above with the notion of a more direct programming of development written into the structure of the genes, our phenomenological knowledge about the regularities of development should be recognised as being just that. □

Continents old and new

from I.G. Gass and J.B. Wright

MANY geological texts and research papers identify two schools of thought when it comes to the subject of the origin and evolution of continental crust. One school, which could be labelled the 'conservationists' or 'reworkers', maintains that virtually all of the continental crust formed during the earliest part of the Earth's history and has been periodically reworked since. Reworking involves remelting and recycling of the original crust but not adding any new increments to it. The alternative 'accretionist' or 'incremental' hypothesis is that continental crust has grown continuously or episodically since the time of preservation of the oldest crustal rocks around 3,800 Ma ago.

A related question is the extent to which plate tectonic processes have operated during the Earth's history. At one extreme is the view that as soon as crust formed at the Earth's surface it was being moved about by plate tectonic processes; at the other extreme are those who maintain that plate tectonics did not begin to operate until late in the Proterozoic. While the meeting seemed to throw up a consensus favouring an incremental model for crustal evolution, opinion about the time of onset of plate tectonics seemed to be as divided as ever.

Several speakers provided evidence to support the thesis that (1) some 70–75% of continental crust was formed during the Archaean (> 2,500 Ma), the remaining

*A discussion meeting, 'The origin and evolution of the Earth's crust', was held in London by the Royal Society on 21–22 February, 1980 and organised by S. Moorbath and B. Windley.

25–30% during the Proterozoic and Phanerozoic; (2) crust-forming magmatic products originated in the mantle; (3) existing continental material had relatively little effect in modifying the composition of magmatic mantle products. Some took plate tectonic processes back to 3.8×10^9 years and correlated Archaean greenstones with Phanerozoic ophiolitic sequences and Archaean granitoids with products of present-day arc systems. Others pointed to geothermal and geochemical differences and argued either that if plate tectonics had existed in the Archaean, the processes were markedly different from those of the present; or that some other mechanism must have been involved.

Some interesting ideas were presented and several speakers dealt with particular aspects of accretionary processes. For instance, J.F. Dewey (Albany, New York), a staunch advocate of Precambrian plate tectonics, invoked the term 'para-oceans' and maintained that mantle processes leading to the formation of basins or para-oceans without reaching the true sea-floor spreading stage, probably make quantitatively important contributions to evolution of the continental crust. W.R. Dickinson (University of Tucson) suggested that sufficient variables exist in present-day plate tectonic processes to explain all the differences identified for older geological formations. Others, notably D.E. Karig (Cornell University), A.M. Ziegler (University of Chicago), W. Hamilton (US Geological Survey, Denver), F. Barker (USGS, Denver), R.S. Thorpe (Open University) and G.C. Brown (Open University), discussed the role of existing crust in modifying mantle products either by the incorporation of subducted sediments or by reaction between ascending magmas and the crust. Most argued that the modifications were quantitatively minor, though it was evident that a fuller understanding of island arc and back-arc processes (J. Tarney, University of Leicester) is essential. In this respect, B. Windley's (University of Leicester) report on an upended Upper Cretaceous arc in the Himalayas (traversed by the new Karakoram Highway), was particularly appropriate (see box). By way of a corrective to those advocating large scale relative movements of cratonic blocks in the Proterozoic, D.J. Dunlop (University of Toronto, Ontario) pointed out that the palaeomagnetic record remains inconclusive.

Geological, geophysical and geochemical modelling attempts to place restraints on the shape, form and composition of continental crust and hence on the processes that form it. E.R. Oxburgh (University of Cambridge) and P.R.A. Wells (Shell, The Hague) presented thermal models relating to the thickness of continental lithospheric plates and the

An island arc section in the Himalayas

from Mike Coward, Geoffrey King and Brian Windley

THE newly-constructed Karakoram Highway in Pakistan provides access to (and excellent exposure of) the magnificent Kohistan island arc section. A recent conference of an International Geodynamics Working Group* provided much information on the geological and structural setting of the Kohistan island arc as well as a visit to the site.

At the conference Qasim Jan and K. Tahirkheli (University of Peshawar) and the French group from the Geology Department, Montpellier University described the structure cut by the Karakoram Highway in the Kohistan Himalayas. They interpreted this as a complete section of a late Cretaceous island arc, standing on end. At the base of the section, garnet and pyroxene rocks interpreted as mantle are overlain by amphibolite and metagabbro. Above this is a huge elongate layered metanorite lopolith at least 15 km thick and 300 km long. Above this and apparently related to it are calc-alkaline intermediate and acid intrusive and volcanic rocks topped by a magnificent section of pillow lavas and volcanic derived sediments.

This is the first complete section of continental style crust to be identified. It

*Held at the University of Peshawar, Pakistan on 19–27 November, 1979.

extent of under and overplating above destructive margins. Oxburgh argued that the continental lithosphere can be at most 250 km thick, a conclusion contested by T.H. Jordan (Scripps Institution, San Diego) who presented evidence that the lithosphere (tectosphere) beneath cratonic areas may be up to 400 km thick. However, this geologically reasonable model was strongly challenged by other geophysicists in the audience. Two contributions by H.D. Holland (Harvard University) and S.R. Taylor (Australian National University) respectively discussed the role of the atmosphere and hydrosphere and of sediments in crustal evolution; and J.V. Smith (University of Chicago) rounded off an interesting session with some speculations about the first 800 Ma of geological time (between 4,600 and 3,800 Ma ago).

The afternoon of the second day proved the most controversial part of the whole meeting. Chaired by the unashamedly 'accretionist' S. Moorbath (University of Oxford) it opened quietly enough with an exposition of the role of fluids, both magmatic and volatile, in crustal evolution (G.N. Hanson, State University of New York, Stony Brook). R.L. Armstrong (University of British Columbia) ably and entertainingly stated the 'conservationist' case, using evidence from a wide variety of sources, to support his thesis that the

is still apparently being emplaced as a massive thrust slab imbricated between the plate to the north carrying the Karakoram granite and thrust slabs of the Indian subcontinent. During the thrust process, which continued seismicity suggests is still active, the Kohistan sequence has been tilted so that the layering and bedding are vertical.

Future work on the exposed section will allow the chemical differentiation process in island arcs to be studied. Some aspects of the process are already obvious and interesting. Since the lopolith from which the higher level andesitic rocks derive is basic in composition, it seems that andesitic differentiation to form calc-alkaline rocks occurs at crustal levels rather than deeper in the mantle and the details of this can be studied.

Further studies of structure and seismicity should also elucidate the processes whereby dense material can be lifted by thrust processes to high crustal levels and may also indicate the depth at which decoupling occurs in lower lithosphere.

continental crust has not grown significantly since early Precambrian times, but has been quantitatively recycled since it was first fully formed early in the Earth's history.

The discussion which followed showed this school of thought to be in a minority, but it also demonstrated that the difference between the two schools may be more imagined than real: few would dispute that there is some recycling of continental crust, the question seems to be simply: 'how much'. On the basis of some crustal modelling, R.K. O'Nions (University of Cambridge) argued that although most continental crust formed by about 3×10^9 years ago, the relationships between Nd, Sr, and Pb isotopes are consistent with a small amount of crustal recycling.

Finally D.P. McKenzie (University of Cambridge) focused on the geophysical constraints on models for the early Precambrian, when heat generation was much greater than now, and provided a salutary reminder that crust and lithosphere cannot be treated separately when discussing crustal evolution.

All in all, there was little if any 'crossing the floor' at this meeting, the protagonists seem to have gone their separate ways unconvinced by each other's counter-arguments. But this was a timely, entertaining and authoritative review of the contrasting lines of thought. □

Particle beam weapons—
a technical assessment

G. Bekefi, B. T. Feld, J. Parmentola & K. Tsipis

Program in Science and Technology for International Security, Department of Physics, Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139*This article explores the feasibility of particle beam weapons, identifies the physical principles that would govern their operation, assesses the technical difficulties, and evaluates their potential uses.*

THE US and the Soviet Union are thought to be working on the design of particle beam weapon systems¹⁻³. We describe here the physics of the generation, propagation, and interaction with a target of a beam of particles intense enough to inflict damage or destroy the target. We analyse the operational aspects of a particle beam weapon system: Who could use it and for what missions. How one could track the target and aim the beam with accuracy dictated by the zero-miss requirement inherent in this type of weapon. How the damage inflicted on a target could be assessed. How the entire weapon system could be commanded and controlled, and what countermeasures could be used against it. Laser beam weapons are not considered.

We examine the possibility of an energetic beam of particles as a weapon system with either exoatmospheric or endo-atmospheric applications. Based on a satellite orbiting about the Earth, the weapon could be used to shoot down intercontinental ballistic missile (ICBM) boosters in the powered-boost phase of their orbits, after they have ascended above the atmosphere. It could also be used to attack space-borne assets of another country. And, it could attack individual reentry vehicles (RVs) as they speed towards reentry into the atmosphere shortly before they reach their intended targets. An endoatmospheric particle beam based on the ground could defend point targets such as missile silos against reentering warheads or, if placed on a ship, could defend it against cruise missiles.

For use against ICBM boosters, the particle beam weapon could be deployed on an orbiting platform either in a near-Earth orbit of $\sim 1,000$ km above the Earth's surface, or in a geosynchronous orbit, at an altitude of $\sim 40,000$ km. From the latter orbit two satellites would suffice for continuous Earth-wide coverage of all possible ICBM or submarine launched ballistic missile (SLBM) launching sites. From a 1,000 km orbit, assuming horizon-to-horizon coverage, one would require a minimum⁴ of 29 platforms with particle beam weapons. A more realistic value for the angular coverage gives⁴ 120 as the number of platforms. In all cases, to be effective as an ABM system, each weapon would have to neutralise $\sim 1,000$ missiles during the first 5 min of their flight; that is, the system must be capable of destroying one target every 0.4 s. Unlike an antiballistic missile (ABM) system that uses missiles with nuclear warheads, a particle beam weapon requires a direct hit on the target to destroy it. As the characteristic length of an ICBM booster is of the order of 10 m, and the distance to it from the platform typically 1,000 km, the beam would have to be aimed with an accuracy of better than 10 p.p.m., that is, $\sim 1,000$ times more accurately than what an ordinary ABM system requires. Also, the system would need to be designed to fire several times per second at any one of the 1,000 targets, adjusting the aim each time to compensate for the miss distance of the previous shot.

Alternately, a particle beam weapon system based on orbiting platforms could be used to attack ballistic reentry vehicles that carry nuclear warheads to US targets. This approach for ballistic missile defence has no advantages over one designed to attack

the missile boosters. Reentry vehicles are considerably smaller than an ICBM booster, which complicates the problem of their detection, identification, and the aiming accuracy. Although they may be targetable from an orbiting platform for more than a few minutes, their large numbers (the Soviet Union is deploying missiles with 8–10 RVs per booster) require faster system response.

A third exoatmospheric use of a particle beam weapon would be as an anti-satellite system. When used for long-range applications against satellites in very high orbits above the Earth, the system would encounter the same problem of beam aiming and tracking as in the ABM use, except that in this case the target could be held under attack for a long period of time.

Endoatmospheric applications would include ground- or ship-based systems either for the point defence of silos against reentry vehicles, or of ships against cruise missiles. An ICBM RV on a normal trajectory would rise above the radar search horizon some 4,000 km, or ~ 10 min travel, away from the radar. For a cruise missile travelling near the surface at a speed of Mach 1, the radar detection distance could be as short as 1 km or about 4 s away.

To determine the performance parameters and physical characteristics of a particle beam weapon we began at the target, by first calculating the amount of energy that would damage a target, then examined the propagation of a particle beam through the atmosphere or the vacuum of outer space, and finally specified the characteristics the beam must have at the exit of the accelerator. On the basis of such considerations, one can calculate the required parameters of the accelerator.

Our assessments sometimes use idealised models of, often, very complex physical phenomena. However, our calculations tend to overestimate the effectiveness of the beam as a weapon.

Damage mechanisms and energy deposition on target

To determine the energy per unit area that the particle beam must deposit to be an effective weapon, one must consider the mechanisms by which deposition of this energy on a target would destroy it or cause it to malfunction. The mechanisms considered are: boring a hole in the outer shell of the ICBM or cruise missile, melting or damaging the guidance and/or control electronics of any of the targets; or exploding the high explosive trigger(s) of the nuclear warhead(s) carried by an ICBM or cruise missile.

A charged particle can cause chemical explosives to detonate by several cooperative mechanisms. Most chemical explosives will explode if their temperature is raised to $\sim 500^\circ\text{C}$ when confined. In the presence of the beam, this threshold temperature may well be lower, because of electric field and shock wave creation within the material. Thus, $\Delta T = 500^\circ\text{C}$ is a conservative figure. The energy density ϵ required to detonate the explosive is then given by $\epsilon = 3Rp\Delta T/M$ where R is the universal gas constant, and ρ and M are the mass density and

molecular weight of the explosive, respectively. Taking $\rho = 0.8 \text{ g cm}^{-3}$ and $M = 50$, yields $\epsilon = 250 \text{ J cm}^{-3}$. Similarly, knowing the specific heat, melting temperature and the heat of fusion of materials, the energy density necessary to melt them can be computed. To melt the aluminium shell of the weapon requires $\epsilon \approx 3,200 \text{ J cm}^{-3}$ and to melt the silicon substratum of electronic components requires $\epsilon \approx 7,000 \text{ J cm}^{-3}$.

Electronics, however, are not only sensitive to catastrophic failure due to an increase in temperature. Rate-dependent effects, caused by the creation of a large number of electron-hole pairs generated during the passage of a charged particle beam through the electronics, can also destroy the circuits. For example, recombination of the pairs could generate enough heat to damage circuit elements. The threshold for this effect in silicon is $\sim 10^{13} \text{ rad s}^{-1}$ or $2.4 \times 10^8 \text{ J cm}^{-3} \text{ s}^{-1}$. Thus, a beam that could deliver 10^3 J cm^{-3} in $1 \mu\text{s}$ could damage electronic circuits via this mechanism. Alternatively, production of ions which are trapped inside the microcircuits can form inversion layers which interrupt operation. Incident radiation can shift switching thresholds and cause source leakage in metallic oxide silicon circuits, which drains the power supply. Switching times can be affected: an energy deposition of $\sim 25 \text{ J cm}^{-3}$ would be enough to cause havoc in the guidance or control electronics of a missile or satellite. These results are summarised in Table 1.

Table 1 Estimated minimum deposition energy densities on various targets

Material	Type of damage	Energy density ϵ (J cm^{-3})
Aluminium	Melting	3,200
Chemical explosive	Detonation	250
Silicon	Melting	7,000
Silicon	Electron-hole recombination in circuits	1,000
Semiconductors	Shifts in circuit switching thresholds and times	25

The total energy E that must be deposited on target to cause damage is given by $E = \epsilon l A$ where ϵ is the appropriate energy density as given in Table 1; $l \equiv E \text{ dz/dE}$ is the scale length for energy absorption, that is the distance over which the beam particles are degraded in energy to $(1/e)$ th of their initial value, as a result of passage through the medium; A is the cross sectional area of the beam illuminating the target, and depends on the optics of the beam but not on target size.

A beam for a functional weapon seems to be one with $\epsilon \approx 1,000 \text{ J cm}^{-3}$ and $A = 10^4 \text{ cm}^2$. With $l \approx 9 \text{ cm}$, a value appropriate to the passage of an electron beam of several hundred MeV through aluminium, one obtains $E \approx 100 \text{ MJ}$. This then, is the energy that must be supplied by the accelerator. If V is the beam voltage, I the beam current, and τ the pulse length, we have that $E = VI\tau = 10^8 \text{ J}$. Setting $V = 10^9 \text{ V}$ and τ , say, equal to $100 \mu\text{s}$, gives $I = 1,000 \text{ A}$. Note that if the beam is to have a cross-sectional area $A = 10^4 \text{ cm}^2$ on a target $1,000 \text{ km}$ away, the required angular beam divergence is only 10^{-6} rad , which is a very demanding accelerator beam emittance.

Exoatmospheric propagation of a particle beam

We now examine three effects which impede the propagation of the charged particles in the vacuum of outer space, and then consider systems using neutral beams.

Electron and proton beams: The first effect is the radial spreading of a charged particle beam caused by Coulomb repulsion between like charges. Using relativistic particle dynamics, one finds that the beam radius a at a distance z from the source is

determined from the expression,

$$aF(\ln(a/a_0)^{1/2}) \approx (z/\beta\gamma)(I/I_A)^{1/2} \quad (1)$$

where a_0 is the initial beam radius and F is Dawson's integral⁵; $\beta = v/c$ with v as the axial particle velocity, and $\gamma = [1 - (v/c)^2]^{-1/2}$. I is beam current and I_A the Alfvén current defined as⁶

$$\left. \begin{aligned} I_A &= 4\pi\epsilon_0 m_0 c^3 \beta\gamma / e \\ &= 1.70 \times 10^4 \beta\gamma \text{ A for electrons} \\ &= 3.12 \times 10^7 \beta\gamma \text{ A for protons.} \end{aligned} \right\} \quad (2)$$

For a $1,000 \text{ A}$, 1 GeV electron beam having an initial radius of 1 cm , and striking a target at a distance $z = 10^3 \text{ km}$, equation (1) yields $a \approx 15 \text{ m}$. For an identical proton beam, $a \approx 1.8 \times 10^4 \text{ m}$. Therefore, while electron beams cannot be entirely ruled out as a weapon by this phenomenon alone, proton beams would obviously have no practical use.

The second effect which interferes with the use of charged particle beams in outer space is the deflection they suffer in the Earth's dipole magnetic field. In a uniform magnetic field \mathbf{B} , the radius of curvature⁷ $R = (m_0\beta c/eB)\gamma$. Hence a 1-GeV electron beam directed from a $1,000 \text{ km}$ orbit above the Earth towards a target $100\text{--}200 \text{ km}$ above the Earth's surface will have a radius of curvature in the geomagnetic field of $\sim 110 \text{ km}$. A corresponding proton beam will have a 190 km radius of curvature. Therefore, these beams will never reach the target $1,000 \text{ km}$ away. We show below that higher energies will be of no use.

Charged particle beams are deflected from their original direction by the geomagnetic field. The uncertainty ΔR in the position of a 1-GeV electron beam due to an uncertainty of 1% of the value of the geomagnetic field is 100 m at a $1,000 \text{ km}$ range, as obtained from the equation $\Delta R = R(\Delta B/B)$. This forbids the aiming of the beam. Another serious problem is that the geomagnetic field can be greatly and unpredictably disturbed by a nuclear explosion in the stratosphere.

The alternative is to use neutral particle beams for exo-atmospheric applications. We have considered neutron, γ -ray, and neutral hydrogen beams. The first two are unsuitable because the beam divergence is intolerably large. The neutral hydrogen beam is more promising.

Neutral hydrogen, H^0 , beams: A neutral hydrogen beam is generated from an H^- beam, that is, hydrogen atoms with one extra electron. Beams of these particles can be accelerated⁸ to $\sim 500\text{-MeV}$ energies in circular accelerators with a confining magnetic field of $\sim 10,000 \text{ G}$. The maximum energy achievable by this process is limited by the Lorentz force. That is, the particle feels an electric field of magnitude $q|\mathbf{v} \times \mathbf{B}|$ which causes distortion of its atomic potential and, if sufficiently large, leads to subsequent breakup of the atom. In a linear accelerator, because of relativistic effects, it is difficult to achieve energies $\geq 800 \text{ MeV}$.

The beam of H^- particles is passed through a system of magnetic lenses to focus and aim it. It is then neutralised by removing the extra electron by various methods such as passing it through a gas stripper, the Lorentz force generated by an externally imposed magnetic field, a plasma cell, or by ejecting one of the bound electrons with a laser beam. The gas-stripper approach seems to be the most direct. The cross-section for the stripping reaction is large (typically one-tenth of the geometric cross-section of the atom) and the efficiency^{9,10} of converting H^- to H^0 can be as high as 50% after passage through a few microgrammes of gas. To estimate the minimum divergence θ of the H^0 beam, we assume that the incident H^- beam has zero transverse momentum when incident on the gas stripper. From the uncertainty principle it is readily shown that $\theta \approx 2[(m_0/M)E_{\text{H}^-}/E]^{1/2}$ where m_0 is the electron mass, M the proton mass, E_{H^-} the binding energy ($\sim 1 \text{ eV}$) of the electron in the H^- ion, and E the energy of the beam. Setting $E = 500 \text{ MeV}$, gives $\theta \approx 2 \times 10^{-6} \text{ rad}$, a value which is sufficiently small to make the neutral hydrogen beam of potential weapon interest.

There are, however, several problems. First, the beam divergence calculated above represents a lower limit as it ignores the divergence of the incident H^- beam; the total angular spread due to the addition of spreads from two (independent) sources is given by $(\theta_0^2 + \theta^2)^{1/2}$ where θ_0 is the spread of the incident H^- beam. Therefore, it is not certain that accelerator technology will make it possible to construct an accelerator having the necessary small emittance, large beam current, and large beam energy. Second, if the beam size is to be maintained, the magnetic lens that bends the beam must be achromatic to 1% or better and have a stable and predictable field strength to 1 p.p.m., requiring that the system of magnets be carefully shielded from the geomagnetic field. And third, the determination of the miss vector is very difficult with a neutral beam.

One can also generate a neutral beam through the capture of electrons by a beam of positive ions, leading to the formation of "plasmoids". However, such beams have large beam divergencies and are not suitable for weapon use.

Endoatmospheric propagation of a particle beam

When a charged particle beam is fired into the atmosphere, it partially ionises the gas in its immediate neighbourhood. The plasma thus generated helps to reduce the radial electric field associated with the primary beam, to the point that it is balanced by the beam's self-magnetic field. In principle, then, it is possible to propagate a charged particle beam in the atmosphere. In the following we examine its propagation characteristics.

Beam propagation: The magnitude of the allowed beam current I is constrained by the fact that as the current in, say, a cylindrical beam increases, so does its self-generated azimuthal magnetic field B_θ . An individual beam electron subjected to this field will undergo radial oscillations, and if I and thus B_θ are large enough, it will be deflected backwards⁶, opposite to its initial (axial) propagation direction. When the beam is completely space charge neutralised by the presence of the ambient ionised gas, and if moreover the beam has a uniform density over its cross-sectional area, one then finds⁶ that the maximum allowable current I_{\max} is the Alfvén current I_A given by equation (2). However, by proper beam shaping^{11,12} (for example, using a hollow, annular beam) I_{\max} can substantially exceed I_A . When a uniform beam is partially space charge neutralised, with a neutralisation factor f ($0 \leq f \leq 1$), the appropriate maximum current is now given by¹³

$$I_{\max} = 17,000 \beta^3 \gamma / (\beta^2 + f - 1) \text{ A} \quad (\text{for electrons}) \quad (3)$$

Equations (2) and (3) refer to infinitely long beams. However, one needs to consider the beam front where a rising current occurs. The time varying current generates a time varying azimuthal magnetic field $B_\theta(t)$ which in turn produces a time varying electric field $E_z(t)$ that drives a counterstreaming current in the ambient plasma. This is referred to as 'current' or 'magnetic neutralisation'. When magnetic neutralisation is complete (that is, the forward primary beam current equals the induced counterstreaming current) I_{\max} is unlimited in magnitude. If, however, magnetic neutralisation is only partial, one finds that,

$$I_{\max} = 17,000 \beta \gamma / (1 - f_m) \text{ A} \quad (\text{for } f = 1) \quad (4)$$

where f_m is the fractional magnetic neutralisation factor, $0 < f_m < 1$.

Knowledge of the magnitudes of f and f_m and of beam propagation characteristics in general requires detailed knowledge of ionisation cross-sections of atmospheric constituents and of beam dynamics. Partial (or complete) space-charge neutralisation f comes about through two processes: by direct ionisation of the gas by the beam, and by avalanching in the induced electric field¹⁴. In addition to these 'classical' processes, and at pressures below ~ 1 torr, ionisation by microinstabilities is prevalent. Here electron generation occurs as a result of the

strong turbulent electric field associated with the instabilities^{15,16}.

A typical experimental value of the ratio n_p/n_b of the secondary plasma density to primary beam density is, $10^3 \leq n_p/n_b \leq 10^4$. For example, when the beam current density $J_b = 1 \text{ kA cm}^{-2}$, $n_b = J_b/ec = 2 \times 10^{11} \text{ cm}^{-3}$ and it follows that $2 \times 10^{14} \leq n_p \leq 2 \times 10^{15} \text{ cm}^{-3}$. As relevant gas pressures lie in the range 4×10^{16} to $3 \times 10^{19} \text{ atom cm}^{-3}$ (atmospheric pressure), we see that the ambient gas becomes weakly ionised (degree of ionisation $\leq 2\%$), and the beam forms an electrically conducting channel of conductivity σ , where

$$\sigma = n_p e^2 / m \nu \quad (\text{S m}^{-1}) \quad (5)$$

Here ν is the electron-atom collision frequency for momentum transfer (for air¹⁷ $\nu = 1.8 \times 10^{-7} n_g \text{ s}^{-1}$ where n_g is the gas atom density in cm^{-3}). At $p = 2 \text{ Torr}$, $n_g = 7 \times 10^{16} \text{ atom cm}^{-3}$, and setting $n_p = 2 \times 10^{14} \text{ cm}^{-3}$, yields $\sigma = 460 \text{ S m}^{-1}$.

Magnetic neutralisation f_m becomes possible¹⁸ when the conductivity σ is large enough, enabling charge of the ambient plasma to move in the axial electric field E_z generated by the propagating electron beam. This electric field drives the return current I_r , whose current density is $J_r = \sigma E_z$. The magnetic neutralisation factor $f_m \equiv J_r/J_b$ is then given by $f_m = \sigma E_z/J_b = \sigma V/J_b L$ where V is the axial voltage drop along the beam, and L is its length. Setting $f_m = 1$, $\sigma = 460 \text{ S m}^{-1}$ and $J_b = 10^7 \text{ A m}^{-2}$, yields an axial electric field $E_z = 2.2 \times 10^4 \text{ V m}^{-1}$. We observe that the axial electric field causes an energy degradation of the primary beam. In going 1 km, each beam electron loses 22 MeV, a 2% energy loss from a 1 GeV beam. This, of course, is not the only energy loss¹⁹ by the beam particles.

Table 2 summarises qualitatively the propagation characteristics¹⁸ of an electron beam. Much experimental and theoretical work is needed for a clear understanding of this very complex problem.

Table 2 Propagation characteristics¹⁸ of an electron beam in air*

Air pressure (torr)	Typical value of f	Typical value of f_m	Beam behaviour
$< 10^{-3}$	≈ 0	≈ 0	Beam blows up
$\approx 10^{-1}$	≈ 1	$\ll 1$	Beam pinches
≈ 1	1	≈ 1	Beam drifts in a force-free environment
> 20	1	≈ 0	Beam pinches and then breaks up

* $V \approx 3 \text{ MeV}$, $I_b \approx 50 \text{ kA}$, pulse length $\approx 30 \text{ ns}$

Beam dispersion: Consider first an electron beam. To determine the increase in area along the beam axis caused by scattering, we assume that the beam is fully space-charge neutralised and that the ratio of beam current, I_b , to the Alfvén current, I_A , is $\ll 1$. This corresponds to the paraxial ray approximation for which the transverse particle velocity is small compared with the longitudinal velocity. The beam current density and the fields are taken to be azimuthally symmetric, with no density variations occurring across a transverse segment of the beam. The energy of the beam particles is assumed to remain constant, independent of distance. Only small-angle multiple scattering is considered, beam segments do not overtake one another in the direction of propagation, and effects of return current are neglected. Particles interact with each other by the collective fields they induce. All relevant time scales are long compared with the period of particle oscillation. In these conditions one obtains a form of Nordsieck's equation^{20,21} given by

$$(I_b/I_A) \ln [R^2(z)/R_0^2] = \langle \theta_s^2(z) \rangle - \langle \theta_0^2 \rangle + O(d^2 R^2/dz^2) \quad (6)$$

where I_b is the beam current and I_A the Alfvén current given by equation (2). $R(z)$ is the beam radius at some axial distance z , and R_0 is the beam radius at the injection point $z = 0$. The quantity $\langle \theta_s^2(z) \rangle$ is the mean square scattering angle due to scattering by the background gas and $\langle \theta_0^2 \rangle$ is the mean square

angle of the random component of the particle motion at the point of injection, $z = 0$. It is related to the accelerator emittance ϵ through²⁰

$$\langle \theta_0^2 \rangle = (\epsilon/R_0)^2 \approx (I_b/I_A) \ll 1 \quad (7)$$

For small beam spreading, the term $O(d^2 R^2/dz^2)$ appearing in equation (6) can be neglected.

The mean square scattering angle is given by²²

$$\delta \langle \theta_s^2 \rangle / \delta z = c_1 \ln(c_2 z^{1/2}) \quad \left. \begin{aligned} c_1 &= (8\pi e^4 Z(Z+1)n) / (m^2 c^4 \gamma^2 \beta^4) \quad \text{cm}^{-1} \\ c_2 &= (hZ^{2/3} n^{1/2}) / (\pi^{1/2} m c \beta) \quad \text{cm}^{-1/2} \end{aligned} \right\} \quad (8)$$

where Z is the atomic number of the gas (equal to ~ 7.4 for air) and n is the density of nuclei (equal to $2.69 \times 10^{19} \text{ cm}^{-3}$ at sea level). Integrating equation (8) with respect to z , and inserting the result in equation (6) yields

$$R^2(z)/R_0^2 = A(z)/A_0 = \exp [I_A/I_b (c_1 z \{ \ln [c_2 z^{1/2}] - 1/2 \})] \quad (9)$$

where $A(z)$ is the cross-sectional area of the beam at position z and A_0 is its area at the accelerator, $z = 0$.

The larger the beam current (consistent with $I_b/I_A \ll 1$) the smaller the beam dispersion. We take as an example our model beam: beam voltage = 1 GeV, beam current = 1,000 A. Then, at a distance z of 1 km, equation (9) gives $A(z=1 \text{ km})/A_0 = 7.0 \times 10^7$. A beam which is initially, say, 1 cm in radius expands to 84 m in a distance of 1 km. Note, however, that this is an optimistic lower limit on the dispersion suffered by the beam. For beams with energies ≥ 100 MeV, the principal energy loss¹⁹ is through bremsstrahlung. The beam energy degrades rapidly as a result of this loss, and if E_0 is its initial energy, then at a distance z , $E(z) = E_0 \exp(-z/z_0)$ where for air the 'radiation length' $z_0 \approx 300$ m. As a result, the scattering increases since in accordance with equation (8), $\delta \langle \theta_s^2 \rangle / \delta z$ varies as $[E(z)]^{-2}$. Thus, even in a distance z as short as one radiation length, the electron beam disperses hopelessly.

Now consider a proton beam with the same specifications of energy and current (1 GeV, 1,000 A). Blanchard²³ obtains for the mean scattering for heavy particle incident on matter,

$$\langle \theta_s^2 \rangle = \langle \theta_0^2 \rangle + 2\kappa Z(m_e/m_p) \ln \left[\frac{E_0(E + 2m_p c^2)}{E(E_0 + 2m_p c^2)} \right] \quad [10]$$

where E_0 and E are the proton kinetic energies at the beginning and the end of the path, respectively, and κ is a coefficient of the order of 1 (≈ 0.75 for air), having a weak dependence on the nature of the ambient medium and on the proton energy. Using the results of Bethe and Ashkin²⁴ for proton energy loss due to both hard and soft collisions, one finds, for protons with an initial energy $E_0 = 1$ GeV, a loss of ~ 130 MeV in traversing 1 km of atmosphere. Hence $E = 870$ MeV and equation (10) yields $\langle \theta_s^2 \rangle \approx \langle \theta_0^2 \rangle + (5.5 \times 10^{-4})$. Substituting this result in equation (6) and noting that for protons $I_A = 3.12 \times 10^7 \beta \gamma A$ (see equation (2)), it follows that $A(z=1 \text{ km})/A_0 \approx 10^{13}$. Beam dispersion is immense. Indeed, A/A_0 is so large that equation (6) from which this ratio was derived has long ceased to be valid. What actually happens is that the protons do not propagate as a beam but form a cloud of positive charge near the outlet of the accelerator. In addition, above 1 GeV, endoatmospheric propagation of protons is limited primarily by nuclear collision which results in a particle number loss from the beam.

Hole-boring: The above results indicate that electron or proton beams are not suitable for endoatmospheric transport of energy over any distances useful for a weapon. An alternate approach is to attempt to bore an evacuated channel through the intervening atmosphere to the target through which a particle beam could propagate. This reduces the density n of scatterers and thus the scattering angle θ_s (see equation (8)).

To calculate the amount of energy that will be removed from the beam to bore a hole, consider a pulsed 1-kA electron beam of 1-GeV energy. The particles will lose energy by two effects: ionisation and bremsstrahlung. For air at STP, the ionisation loss

is²⁵ $\sim 2 \times 10^3 \text{ eV cm}^{-1}$ for energies of ~ 1 GeV. The ratio of radiation loss to collisional loss is determined by the Z of the scattering material and the energy of the beam, and is roughly $EZ/1600 m_0 c^2 \approx 9.1$.

Take a beam with an area $A_0 = 1 \text{ cm}^2$ at the accelerator port and an initial current I_b of 1.0 kA. The beam will then deposit energy by ionisation at a rate of $2 \times 10^6 \text{ W cm}^{-3}$ and by bremsstrahlung (mainly in the forward direction) at a rate of $1.8 \times 10^7 \text{ W cm}^{-3}$. Both of these effects will contribute to superheating of the air in the region of the beam, and the consequent formation of a channel of reduced density through which successive pulses could pass. This is the concept of hole-boring. To reduce the gas density in the channel to, say, $0.1 \times$ atmospheric density, the temperature must rise to $\sim 3,000^\circ\text{C}$. For a channel of 1 cm^2 cross-sectional area and 1 km long, the beam must deposit an energy of $\sim 1.5 \times 10^6 \text{ J}$.

By reducing the air density in the channel from atmospheric to $0.1 \times$ atmospheric, the radiation length for bremsstrahlung loss by electrons increases from ~ 300 to $\sim 3,000$ m. Thus, in propagating 1 km, energy loss can be neglected, and γ of equation (8) remains essentially constant. Beam dispersion is calculated in the same way as was done in the previous subsection. For a 1-GeV, 1-kA electron beam one finds that $A/A_0 = 4.4$, which is an acceptably small spreading for weapon use.

Hole boring is indeed necessary for stable beam propagation. Table 2 and experiments^{14,26} indicate that there is a range of pressures within which stable electron beam propagation may exist. For air at room temperature the 'pressure window' extends from ~ 1 to 10 torr. The good propagation characteristics are interpreted²⁷ as a combination of two effects: the quenching of a two-stream instability by sufficiently high plasma density and electron-atom collisions; and the simultaneous suppression of the resistive hose instability caused by sufficiently high electrical conductivity generated by the ionisation processes described earlier.

Endoatmospheric electron beam propagation might, therefore, be an interesting candidate as a weapon, provided that a hole can be bored through the atmosphere that would have a neutral density n around 0.3 to $3 \times 10^{17} \text{ cm}^{-3}$. The crucial question is will the beam remain in the channel over distances of, say, 1 km? Reported experimental work^{14,26} on this problem involves laboratory measurements over propagation distances less than several metres, and with beams having energies of the order of 10 MeV. Little is known about electron beams with energies in the GeV region.

Accelerator characteristics

There are two types of accelerators in existence: (1) conventional high voltage, low current machines capable of delivering high quality beams of modest energy per pulse; and (2) accelerators based on novel technology^{28,29} developed during the 1960s. The latter are characterised by relatively low voltages, but high currents and exceedingly large beam energies. The properties of the two types of accelerators are summarised in Table 3, together with a list of parameters desirable in an accelerator meant for a particle beam weapons system: the parameters of existing machines are far removed from the needs of a weapon's type of generator.

An exoatmospheric particle beam weapon requires a machine that would accelerate a beam of H^+ atoms to about 1,000 MeV. H^+ ion beams are routinely accelerated in proton linear accelerator systems at the Argonne National Laboratory and at the Los Alamos Meson Physics Facility. Recent developments in ion source technology, both in the US and the USSR⁶, indicate that high-current/low-emittance H^+ atom beams are possible, with currents of ~ 0.15 A, and a beam divergence of $\sim 20 \mu\text{rad}$. As the current is at least three orders of magnitude less than that of what a beam weapon would require, technological developments in the near future are unlikely to achieve the requisite currents (~ 1 kA) and beam divergence ($\sim 1 \mu\text{rad}$) for a beam weapon accelerator.

The electrostatic acceleration of the beam to adequate energy for injection into a r.f. linac is done by several different accelerator types, such as a van de Graaf, and offers no technological problem. The main section of the r.f. linac, however, is a problem. None of the existing machines has all of the properties necessary for exoatmospheric particle beam weapon applications. For instance, the BNL and the Fermi Lab injector linacs both accelerate 0.15–2 A currents in short pulses. Moreover, existing proton linac accelerating gradients are low, $\sim 2 \text{ MeV m}^{-1}$. Experience with electron linear accelerators indicates that gradients of up to $\sim 30 \text{ MeV m}^{-1}$ may be sustained. This makes for extremely long machines when $\sim 1 \text{ GeV}$ beams are desired.

Table 3 Characteristics of the two types of large accelerators, and the desired characteristics of an accelerator for use with particle weapons

Parameter	High-voltage, low-current accelerator	Low-voltage, high-current accelerator	Particle-beam weapon accelerator
Voltage (MeV)	1500	15	1,000
Current (A)	0.025	10^5	1,000
Pulse length (μs)	1.5	0.12	100
Energy per pulse (J)	56	1.8×10^5	10^8
Pulse repetition rate	50 pps	Several per day	≥ 100 pps
Beam divergence (rad)	$\geq 10^{-5}$	$\geq 10^{-2}$	$\sim 10^{-6*}$

* The quoted value of $1 \mu\text{rad}$ is for exoatmospheric weapons systems only; for endoatmospheric use, much poorer emittances would suffice.

Providing adequate power for an accelerator in space should not pose serious technological problems. The detonation of explosives coupled into appropriate generators could provide the power required. A device for staging the energy to the time scale required for an accelerator, with the capacity to store enough energy with easy retrieval at high efficiency and in a short time, would be necessary. Such staging devices are not apparently beyond current technological capabilities. If we assume an (optimistic) energy conversion efficiency from staging system to beam energy via the accelerator of 50%, and an energy conversion efficiency from primary power to the staging system of 30%, the primary power required will be about six times more than the beam power. Therefore, an accelerator that produces a 100-MJ beam (see Table 3) will require 600 MJ of primary energy per pulse. The energy stored in high explosives is $\sim 4 \times 10^3 \text{ J g}^{-1}$, and it follows that the requisite primary energy can be supplied by the explosion of $\sim 150 \text{ kg}$ of high explosives per pulse.

Another type of accelerator, the linear induction accelerator, is capable of short pulses of very high current and has been developed for various applications. A typical linear induction accelerator is the ERA 4-MeV induction linac built in Berkeley. The accelerator produced a current of 1,200 A for 40 ns at an output energy of 1–4 MeV. The system is capable of reproducible high current operation; it is, however, bulky and heavy as it consists of iron or ferrite cores for the transformer coupling. In the Berkeley ERA injector case the energy gradient was 0.73 MeV m^{-1} . Presumably this gradient can be increased to about twice this value, but a 1-GeV accelerator will be at least 400–500 m long, with current technology. For a 1,000 section accelerator the weight of iron required is about 100 tons, a reasonable value. The electron gun system necessary for this accelerator is available, and the emittance is suitable for a small diameter output beam.

The unresolved technical questions are whether the energy gradient in such machines can be increased to the point that the overall size of the accelerator becomes practical, and whether a

few kilohertz pulse rate that seems essential for useful operations can be achieved.

Operational requirements of a particle beam weapon system

The operational requirements that various missions dictate are:

- Detect and track the target(s) with appropriate sensors.
- Identify the target(s) among decoys.
- Point the beam at a target and follow the target.
- Fire the beam towards the target.
- Determine if the target was hit, or not.
- Assess the damage if the target was hit.
- Determine the miss vector if the target was not hit.
- Correct the aiming of the beam by the miss amount.
- Fire the accelerator again.
- Determine the miss distance or assess the damage to the target once again.
- Repeat this cycle until the target is verifiably destroyed.
- Communicate the results to a command center.
- Repeat the cycle with the newly engaged next target.

We consider below the performance requirements of the system in several conditions.

Antisatellite, space-based system: In this case the target object would have to be detected by long-range radar and its position further refined by means of an optical sensor. Since the target is typically a few metres in diameter, the weapon system would require optics with at least a 50-cm mirror to resolve the object 1,000 km away. If the target object is $\sim 40,000 \text{ km}$ away, the mirror would have to be 20 m. Even then, the weapon system could not readily assess either the damage inflicted on the target or the miss vector if the target were not hit, and therefore the weapon's operator has no way of knowing whether or where to re-aim the beam for a second burst. He has two choices: either fire once in a 'blind' fashion and assume that the target is impaired, or fire repeatedly until the target satellite tumbles or explodes.

Antiballistic, space-based system: A space-based boost-phase ballistic missile defence particle beam system would have to have similar subsystems as above for target detection and tracking, beam aiming and damage assessment, but the time constants of this operation are very different from an A-SAT mission. A single particle beam weapon must be capable of detecting, identifying, and tracking as many as 1,000 boosters while still in their boost phase, that is, for at most 400 s. The tracking and aiming mechanism must track each booster with an accuracy of one part in 10^5 . The aiming mechanism for a neutral beam could consist of a precalibrated magnetic lens and of focusing magnets which can be mechanically steered for accurate aiming by means of an optical telescope. This would require an achromaticity of the magnetic system of 10^{-6} so that the beam divergence could be maintained at a minimum. As the variations of the geomagnetic field are not known to such accuracy, the entire magnet complex would have to be magnetically shielded. It is very difficult to ascertain the size of the miss vector between a neutral beam and the target, and it may be necessary to fire repeatedly but blindly at a target until there are visible catastrophic results: the ICBM either explodes or tumbles out of control. An alternative to this lengthy process is to preprogram the weapon to fire stochastically a fixed number of particle pulses at a target and then shift to another one without positive identification of a successful hit.

One may also contemplate tracking the H^0 beam with a laser that would induce resonance fluorescence³⁰ (resonant Rayleigh scattering) in the hydrogen atoms. This would necessitate the use of an as yet unavailable, pulsed, tuneable laser emitting $\sim 1 \text{ J}$ of energy in the $1,000 \text{ \AA}$ wavelength range. The number n of fluorescent photons backscattered into the receiving-transmitting mirror of area A situated at a distance R from the scattering volume V is given by

$$n = \left(\frac{E}{h\omega} \right) \left(\frac{A}{A_p} \right) \left(\frac{r_0}{R} \right)^2 \left(\frac{\omega}{\Delta\omega} \right)^2 N_H V \quad (11)$$

Here E is the laser energy and ω is its frequency; $\Delta\omega$ is the line width of the laser, or of the resonance H^0 transition, whichever is the larger; $r_0 = e^2/4\pi\epsilon_0 m_e c^2$ is the classical electron radius, A_s the cross-sectional area of the scattering volume V , and N_H is the number of density of H^0 atoms. Taking $E = 1\text{ J}$, $\hbar\omega = 10\text{ eV}$ ($\lambda = 1,240\text{ \AA}$), $R = 10^3\text{ km}$, $V = 100\text{ m}^3$, $A/A_s = 0.018$, $\omega/\Delta\omega = 1.1 \times 10^7$, and $N_H = 2.1 \times 10^{13}\text{ m}^{-3}$ (which corresponds to a 1 kA beam of 1 m^2 cross-sectional area), yields $n = 2.3 \times 10^4$, which suffices for detection purposes. Note that in obtaining this value, we chose a diffraction limited beam divergence of 10^{-6} rad and an (optimistic) line width $\Delta\omega = 2\omega^2 r_0/3c$ equal to natural line broadening.

To track the H^0 beam and determine its position requires the laser to have a much greater pulse repetition rate than that (≥ 100 pulses per s) of the hydrogen beam. Knowing the direction of the beam axis does not resolve the problem of target tracking and aiming discussed above.

We conclude that even if an H^- atom accelerator and stripper system that would produce a neutral beam suitable as a lethal mechanism could be built, it would still be technically infeasible to deploy a particle beam weapon system that could be even marginally effective against a massive ICBM attack on the US. It is unreasonable to assume that a boost-phase ballistic missile defence system would operate in a cooperative environment, as it would have to operate mostly within line of sight of enemy territory. We must consider the countermeasures that a military commander could take against the threat of a particle beam space-borne ballistic missile system. The most obvious method would be to destroy or mine the particle beam accelerator. Weapons based in space during peace time are very vulnerable to small explosive charges on small satellites which have been placed in orbit very close to them.

The operations of a space-based particle beam weapon system would probably be closely controlled from the ground. Interfering with the link between the weapon platform and its ground control would effectively nullify the weapon. Another countermeasure is to deny the system knowledge of the precise location of its targets. This could be done either by jamming the radar which the system must use for initial detection and localisation of its targets, or by the use of offset decoys for radar, visible, or IR. For space targets one can use a chaff shroud or umbrella so that even if the particle beam system could detect the general location of the target by radar, it could not see through the shroud. As the chaff or thin aluminium sheets can be carried by the ICBM booster, such countermeasures would be effective in the case of sea-launched as well as land-based ICBMs.

Another effective countermeasure against a neutral hydrogen atom beam weapon based in space is to interpose a thin layer of air between it and the ICBMs that it is designed to attack during their boost phase. The atoms in the neutral hydrogen beam will be stripped of their electrons and become protons. As indicated above, protons of that energy cannot propagate in space as a beam because they disperse rapidly. The stripping cross-section of a 1-MeV hydrogen atom incident on a nitrogen molecules is $\sim 7 \times 10^{-17}\text{ cm}^2$ (refs. 31, 32). The cross-section falls off roughly logarithmically with increasing energy, and we estimate that at 1-GeV the cross-section is $\sim 10^{-17}\text{ cm}^2$. Now consider filling a volume $4 \times 10^{24}\text{ cm}^3$, an area of $2,000 \times 2,000\text{ km}$ and $1,000\text{ km}$ high, with sufficient air molecules to cause stripping. Using the above value of the cross-section, one finds that the mass of air required is $5.5 \times 10^5\text{ tons}$, and the energy necessary to lift it to the requisite height is $2.7 \times 10^{15}\text{ J}$. As 1 g of high explosives has $\sim 4 \times 10^3\text{ J}$, an explosion of a 0.7 Mton nuclear warhead could provide the energy necessary to raise the layer of air that would disperse the particle beam.

Ship-based, counter-cruise missile system: This mission includes the same operations outlined for the exoatmospheric weapon, except that the command and control systems will be integrated into the ship-based weapon and therefore the communications link cannot be interfered with. Another difference is that the counter-cruise missile weapon has only $\sim 3\text{ s}$ to engage and

destroy its target if it starts its attack at 1 km range, and that the number of targets at any instant would be fewer than in the ABM case, perhaps no more than three or four.

If the weapon does not shoot down the missile with the first beam burst, it must track the target and shoot again. It is not clear, however, that the beam can track a target that has any significant angular velocity with respect to the ship. To accomplish that, the beam would have to leave the evacuated channel that it propagated in and bore another very near the previous one. It is not known whether the atmosphere can support stably such a procedure or how this procedure depends on the angular velocity of the target, the size of the channel, the state of the atmosphere in the immediate vicinity of the ship, or how reproducible such behavior could be.

If the attacking cruise missile can manoeuvre in response to an attack by a charged particle beam, an erratic course after a beam burst would not be a definite indication of decisive damage. A certain kill against a cruise missile would be signalled by the explosion of its warhead or the plunging of the missile into the water. The missile then must be fired at until it is killed and that requires tracking capability for the beam. A missile armed with a nuclear warhead can destroy a ship even if it explodes some distance from it, and that may shorten the time available to the defence to destroy it.

The attacker can also use several countermeasures against a ship-borne charged particle beam weapon. For example, a transonic cruise missile without power and a ratio of lift to drag of 7 loses only 2% in velocity in the first 1 km of glide. In these conditions, multiple decoys could be popped out of a cruise missile, all of which would glide towards the target for the last 1 or 2 km , confusing the defence. Cruise missiles attacking a ship could use an ahead-fired smoke rocket to impair tracking by optical systems, or could fire ahead either chaff for countering radars, or even small explosive rockets for disturbing the uniformity of the air ahead, if strict uniformity is required for charged particle beam propagation.

A land-based ABM system using a charged particle beam as a kill mechanism suffers from the same basic vulnerabilities as earlier ABM schemes^{33,34} that utilised missiles as RV interceptors. The fact that a charged particle beam moves very nearly at the speed of light while missile interceptors are only hypersonic, does not remedy these vulnerabilities.

Conclusions

The current state of accelerator technology is reflected in Table 3. There is no machine which combines the high energy, high current, beam achromaticity and normalised emittance required of an accelerator suitable for a weapon system. This does not mean that accelerators with performance characteristics required for a beam weapon system could not be built. But the operational difficulties of a particle beam weapon outlined here seem insurmountable.

The cost-effectiveness of a charged particle beam system must also be compared to alternate systems, as for example, high energy lasers. Exoatmospheric uses of lasers apparently offer a more near-term operational capability, and also involve a much more available technology that one can assess and evaluate. For endoatmospheric uses, charged particle weapons are faced with competing conventional weapons such as guided projectiles, hypersonic missiles, and rapidly firing point-defence guns. Therefore, in an environment of finite resources for military research and development, it seems unwise and wasteful to develop particle beam weapons, before a detailed systems analysis of countermeasures is made. The performance characteristics of such a system do not overcome the vulnerabilities and weaknesses of earlier ABM schemes^{33,34} that used missiles as interceptors, nor do they lend themselves to the development of an effective substitute of these earlier ABM systems.

This article is the result of an informal study conducted in collaboration with G. Brandenburg (M.I.T.), R. L. Garwin (I.B.M.), and E. Knapp (Los Alamos Scientific Laboratories), whom we thank for their invaluable help.

Fission track age of the KBS Tuff and associated hominid remains in northern Kenya

A. J. W. Gleadow

Department of Geology, School of Earth Sciences, University of Melbourne, Parkville, Victoria 3052, Australia

Fission track ages of pumice from the KBS Tuff have been redetermined using carefully controlled etching and counting procedures. Primary igneous zircons from five pumice samples give a mean age of 1.87 ± 0.04 Myr. The presence of detrital minerals of two different age groups has important implications for the controversy over the age of this tuff.

OVER the past 10 yr the Plio-Pleistocene sedimentary basin on the eastern shore of Lake Turkana (formerly Rudolf) in northern Kenya has been the site of an intensive study of early man and his contemporary environment. Hominid remains, other vertebrate fossils and archaeological material have all been recovered in abundance from this area and various aspects of this multidisciplinary research effort have been described recently¹⁻³.

It was realised very early that several tuffaceous horizons occurring within the sedimentary succession could be used to establish a series of radiometrically dated marker horizons⁴⁻⁷. Deposition of these tuffs in their present locations is thought to have occurred rapidly after the eruptions which produced them. Measured ages on the igneous materials can, therefore, be related directly to the stratigraphic ages of the surrounding sediments and the fossils they contain. Figure 1 gives a generalised stratigraphic column showing the relative positions of the major tuffaceous horizons in the Koobi Fora Formation of the East Turkana Basin. Also shown are the approximate positions of a few of the most important hominid and archaeological sites and their relationship to the KBS Tuff.

Results of K-Ar, ⁴⁰Ar-³⁹Ar and fission track dating studies on these tuffs have been controversial and particular problems have been associated with the KBS Tuff. Fitch and Miller⁸ originally dated feldspars from pumice in this tuff at 2.61 ± 0.26 Myr using the ⁴⁰Ar-³⁹Ar method and although further work^{9,10} produced a scatter of ages from 0.52 to 2.64 Myr this remained their preferred age. Curtis *et al.*¹¹, however, obtained mean conventional K-Ar ages of 1.82 ± 0.04 Myr and 1.60 ± 0.05 Myr respectively for tuffs mapped as the KBS in two different areas of the East Turkana Basin. Subsequently Fitch *et al.*^{12,13} revised their former estimate to 2.42 ± 0.01 Myr in apparent agreement with an average zircon fission track age of 2.44 ± 0.08 Myr reported by Hurford *et al.*¹⁴.

Note that the zircon fission track ages of Hurford *et al.* represent the first attempt at dating young zircons of this kind. These ages apparently agree closely with each other but this is

mainly due to the close communication between these authors on track identification and discrimination in these samples. Further work has not supported this consistency but initially produced a much larger scatter of results. It has become clear that this scatter was due to analytical rather than geological factors and that some of the potential difficulties had not been given adequate consideration in the earlier results.

The present study was initiated to overcome this unsatisfactory state of affairs by first establishing reliable fission track ages for zircons from the KBS Tuff. An important component in this project has been the development of improved techniques to overcome the particular problems that arise when dating zircons from geologically young rocks. The ultimate aim is to establish an independent fission track chronology for many of the tuffs in the East Turkana sedimentary basin.

Sampling and methods

None of the so-called tuffs in the East Turkana Basin represents primary pyroclastic deposits. All have been reworked by running water and redeposited as highly tuffaceous sediments. The deposits are not pure volcanic material and have been shown to contain varying amounts of detrital minerals⁷ which could seriously affect attempts at dating. Sampling was therefore restricted to the occasional blocks of pumice (up to ~25 cm across) which are found in some of the tuffs as these represent relatively uncontaminated igneous material. Pumice samples were collected from the KBS Tuff in Fossil Collection Areas 105, 112 and 131 which are shown in Fig. 2. The detailed petrography and mineralogy of some of these samples has been described elsewhere¹⁵. The pumice from Areas 105 and 131 was found to contain small accessory zircon crystals (up to ~450 × 150 μm but mostly much smaller) suitable for fission track dating. No primary igneous zircons were found in pumice from Area 112.

One of the zircon separates originally dated by Hurford *et al.* (FMA517) was reanalysed in this study. These zircons were extracted from a sample of several pumice cobbles by dissolving

the crushed pumice in a mixture of HF and H₂SO₄ and recovering the crystals from the insoluble residue¹⁴. Zircons were extracted from two large single pumice blocks, FMA559 and FMA560, in essentially the same way. A different separation procedure was used for the two remaining samples (7722-numbers) both of which were composite samples of a large number of pumice cobbles. After an initial coarse crushing to <2 mm a panning procedure was used to separate crystals from the pumice. Zircons were then extracted from the phenocryst concentrate using conventional heavy liquid and magnetic techniques and an additional fraction was obtained by acid dissolution of the glass. Two other minerals suitable for fission track dating, apatite and sphene, were also recovered from the pumices but these were found to be almost entirely of detrital origin.

Fission track dating methods for zircons were based on those described by Gleadow *et al.*¹⁶ and the external detector approach for measuring induced tracks was used. Because of the very young geological age of these zircons, particular difficulties arise which are not generally encountered with older materials. As most previous experience with dating zircons has been with much older rocks than those studied here, these difficulties and their potential effect on the resulting ages have not been clearly understood. Some of the factors involved are as follows:

- (1) Very small numbers of fossil fission tracks are found in the zircons. This is exaggerated in the present samples by a much lower than average uranium concentration and often small grain size. The lack of tracks makes it difficult to assess the correct etching time for these zircons.
- (2) The zircons have a very low track etching rate due to the low level of α -radiation damage¹⁶ making it difficult to reveal all the tracks by etching. Also, the zircon grains tend to fall out of their FEP Teflon mounts during the long etching times required.
- (3) Etching of tracks lying in different orientations is highly anisotropic giving rise to etch pits of differing appearance and making identification more difficult.
- (4) Tiny acicular inclusions are present in the zircons from the KBS Tuff which are often of very similar dimensions to etched tracks and can easily be mistaken for tracks.

The anisotropic etching of fission tracks in different crystallographic orientations in zircons with low radiation damage was examined in more detail by progressively etching collimated ²⁵²Cf tracks in a large zircon crystal from the Mud Tank Carbonate in Central Australia. This zircon has a spontaneous track density of about $3 \times 10^6 \text{ cm}^{-2}$ and a correspondingly high level of radiation damage. One part of the zircon crystal was annealed at 850 °C for 1 h to simulate the absence of significant α -damage in the young zircons and to remove all preexisting fission tracks. The ²⁵²Cf tracks were then implanted on a polished (110) cleavage face in two orientations, parallel and perpendicular to the *c*-axis, both dipping at 30° to the surface. Figure 3 shows how one track etching parameter, the track density, varies with

Fig. 1 Generalised stratigraphic column showing tuffs occurring in the Koobi Fora Formation to the east of Lake Turkana in northern Kenya. The approximate positions of some of the most important hominid and archaeological sites are also shown.

Fig. 2 Locality map of the East Turkana Basin showing the numbered fossil collection areas where the fission track dating samples were collected. Shaded areas indicate the older volcanic basement.

etching time for the two sets of ²⁵²Cf tracks compared with that for spontaneous tracks in an identical but unannealed sample of the zircon. The very different etching rates for the differently oriented tracks is obvious. The etched track shapes are also very different for the two orientations. Tracks perpendicular to the *c*-axis etch more readily and may appear quite satisfactory for counting before many of the tracks parallel to the *c*-axis are yet visible. With continued etching the *c*-parallel tracks become more like the acicular inclusions in appearance and great care is needed to discriminate between the two. These experiments enabled criteria to be set up for the reliable identification of etched tracks in all orientations and for their discrimination from spurious track-like features.

A small test mount was then made up of each of the zircons to be dated and this was irradiated with a high density of ²⁵²Cf tracks. This test mount was then etched alongside the main dating mount for each sample and was inspected periodically to judge the etching time required. Etching was continued for sufficient time (up to 100 h in KOH:NaOH eutectic at 210 °C) to ensure that the tracks in the slow-etching orientations were adequately revealed. The appearance of the etched ²⁵²Cf tracks in the auxiliary mount was then used as a guide to the expected appearance of fossil tracks in equivalent crystallographic orientations. This enabled a much more rigorous discrimination to be made between tracks and spurious features. A test of these discrimination procedures was made by 'dating' a sample of pumice zircon (FMA560) which had been annealed at 850 °C for 1 h to remove all spontaneous tracks.

Another significant departure from standard practice with the external detector method was to count every grain in the mount or in a predetermined area of the mount which was acceptable on the usual surface-orientation and etching criteria¹⁷. This avoided the selection of a small number of grains (typically only about five) for counting which is usually made with older (high track density) zircons. While this selection is inconsequential with high spontaneous track densities, it introduces a serious risk of bias where there are only a few tracks per grain or even no tracks in some cases. In addition all fission track counting of all samples was completed before any ages were calculated to guard against the possibility of earlier results influencing the identification of tracks in later determinations. After ~12 months the entire counting procedure, including the choice of

grains to be counted, was repeated for most of the samples as independently as possible from the first count. In this way duplicate, though not totally independent, results were obtained.

Neutron dosimetry procedures and the techniques used for apatite and sphene have been described in detail elsewhere¹⁸. Flux gradients during irradiation were monitored by using two dosimeter glasses. Approximately 1,200–1,600 tracks were counted over each dosimeter. Constants used in the age calculations were: $\lambda_F = 6.9 \times 10^{-17} \text{ yr}^{-1}$, $\lambda_D = 1.551 \times 10^{-10} \text{ yr}^{-1}$, $I = 7.253 \times 10^{-3}$, $^{235}\sigma = 5.802 \times 10^{-22} \text{ cm}^2$. Errors were calculated according to the method of Naeser *et al.*¹⁹ and McGee and Johnson²⁰ and are expressed as 1 standard deviation (σ) throughout.

KBS Tuff primary zircons

Analytical results are shown in Table 1 for primary igneous zircons from two individual and three composite pumice samples from the KBS Tuff. Results are also shown for two standard zircons of independently known age which were included in the same neutron irradiations as some of the KBS zircons. It can be seen in Table 1 that the fission track ages for these zircons from the Fish Canyon Tuff, Colorado (72N8) and the high level Mt Dromedary Intrusion in New South Wales (7822-9) are in excellent agreement with their K–Ar ages calculated using the new constants recommended by Steiger and Jäger²¹.

As expected no features which would definitely be counted as spontaneous tracks were found in the annealed sample of

FMA560 zircon. After annealing this zircon was subject to identical etching, irradiation and counting procedures as the other KBS Tuff zircons. Applying the same criteria as used for the other samples to discriminate tracks from spurious etch-pits, only four features were seen over 15 grains which might possibly have been confused with tracks and none of these were convincing. These would give a maximum contribution of only $0.11 \pm 0.05 \text{ Myr}$ to the age if all had been mis-identified as tracks. As even this background level is considered unlikely this experiment gives greater confidence that a reliable discrimination has been made for the dated KBS zircons.

For two of the KBS pumices (FMA559 and FMA560) sufficient zircon was obtained for more than one mount to be prepared and these were all etched and irradiated separately. Thus three independent age measurements were obtained for FMA559 and two for FMA560 giving eight measurements for the five pumices. Six of these were counted twice with very close agreement between the duplicate measurements in all but one case. For the second irradiation of FMA560 the duplicate results, which were counted over two quite separate sets of grains, are significantly different from each other at the 95% confidence level. The lower result, $1.54 \pm 0.10 \text{ Myr}$, seems anomalous. Excluding this result the zircon ages for the two individual pumice blocks from Area 131 are indistinguishable from each other and give a mean age and standard deviation of $1.85 \pm 0.06 \text{ Myr}$. This mean age is also indistinguishable from the ages of $1.85 \pm 0.06 \text{ Myr}$ and $1.90 \pm 0.08 \text{ Myr}$ obtained for the composite pumice samples from Areas 131 and 105 respec-

tively. The close concordance of ages for the composite samples and those for individual pumice blocks strongly suggests that zircon-bearing pumice of only one age is present in the KBS Tuff.

A possible explanation for the anomalous FMA560 result of 1.54 ± 0.10 Myr may lie in the extreme range of uranium concentrations found in this sample. The 24 grains counted for this determination ranged from 54 to 516 p.p.m. uranium which is greater than for any other sample. This wide range in uranium concentrations is reflected in the high correlation coefficient observed in this case. It has been shown¹⁶ that the track etching rate in zircon varies with the total radiation damage so that

low-U grains etch more slowly than high-U grains for the same age. Thus it is possible that this determination included some low-U grains which were under-etched thereby depressing the combined age. The combined age of just the high-U grains alone (those with greater than the average of 125 p.p.m.) is 1.85 ± 0.17 Myr which supports this explanation.

The locality sampled in Area 105 can be traced directly to the type locality for the KBS Tuff but outcrop of this tuff is discontinuous between Areas 105 and 131. Nevertheless, the correlation is considered quite firm on the basis of stratigraphy⁷ and the compositions of pumice glasses²² and phenocrysts¹⁵. The dating results reported here also confirm the correlation between the two areas and, excluding the anomalous FMA560 value, give a mean age of 1.87 ± 0.04 Myr which is regarded as the best estimate of the fission track age of the KBS Tuff. Inclusion of the anomalous age would lower this mean to 1.83 ± 0.04 Myr which is not significantly different. The preferred mean fission track age of 1.87 ± 0.04 Myr is in close agreement with the mean K-Ar age of 1.89 ± 0.01 Myr reported by McDougall *et al.*²³ and that of 1.83 ± 0.06 Myr calculated from the data of Drake *et al.*²⁴ (all 1σ errors).

Detrital contamination

Some detrital contamination was present in all zircon concentrates dated, presumably from the small amounts of tuffaceous matrix which had worked deep into vesicles and fractures in the pumice. One of the major advantages of the external detector method of fission track dating, however, is that it permits the determination of ages on individual mineral grains, even at very small grain size ($<100 \mu\text{m}$). Thus it is possible to discriminate between the young primary igneous zircons and the old detrital zircons.

Two distinct groups of detrital zircons have been identified in the KBS Tuff and apart from these no other detrital grains have been found. The first consists of very rare zircon crystals which are euhedral and give single crystal ages between 24 and 27 Myr as shown in Table 2. Zircons of this age group were also found in mineral concentrates from pumices in the Tulu Bor Tuff, the Karari and its correlative, the Chari Tuff. Two apatite crystals of closely similar fission track age were found in pumice from the KBS Tuff in Area 105 (Table 2). These inherited zircons are thought to have been derived from a volcanic source probably to

the east or north-east. No detrital ages younger than 24 Myr were found in zircon or apatite concentrates from the KBS Tuff. Miocene volcanics around the southeastern margin of the East Turkana Basin have given ⁴⁰Ar–³⁹Ar ages of 7.5 and 11.8 Myr (ref. 10) but a collection of these rocks proved to be almost totally lacking in zircon so that these are not a potential source of detrital contamination.

The other group of detrital zircons are much more abundant, often making up ~10–20% of these zircon concentrates. These are readily identified by their rounded, water-worn shapes, frequently darker colour and generally high spontaneous track densities. Two other minerals, sphene and apatite, with similar characteristics to these zircons are also found as detrital minerals in the pumice samples. Many of the detrital zircons are at least partly metamict and therefore unsuitable for fission track dating but satisfactory ages were obtained for some of the grains with low uranium concentrations. Table 2 shows fission track ages for all these detrital minerals, each age representing the combined counting results from several similar grains. Zircon and sphene ages from this group all fall in the range 500 \pm 50 Myr which is typical of radiometric ages for minerals from the crystalline rocks of the Mozambique Belt of East Africa²⁵. This is one of the 'Pan-African' mobile belts of late Precambrian–early Palaeozoic age and form the basement complex of the northern Kenya region.

Detrital apatites from the KBS Tuff in Area 105 (7722–108) give a combined age of 83 \pm 5 Myr which is not obviously related to either the 'Pan-African' detrital ages or the younger 'volcanic' detrital ages. However, apatites frequently give much younger fission track ages than sphenes or zircons from the same rocks due to the much lower thermal stability of tracks in apatite. Table 3 shows ages for apatite, sphene and zircon separated from basement gneisses of the Mozambique Belt from various parts of Kenya as shown in Fig. 4. It can be seen that sphene and zircon both show typical 'Pan-African' ages (500 \pm 50 Myr) but apatites give much younger ages ranging from 62 to 127 Myr with a weighted mean of 82 Myr. This pattern is almost identical to that found in the East Turkana detrital minerals. Thus it seems that the old detrital component found in the pumice samples has probably been derived from basement rocks of the Mozambique Belt.

Significance of the results

Two conflicting hypotheses have been offered to explain the different K–Ar and ⁴⁰Ar–³⁹Ar feldspar ages obtained for the KBS Tuff. Fitch *et al.*¹² consider the younger ages (~1.8 Myr) to be the result of a partial or total over-printing event. Curtis *et al.*¹¹, on the other hand, regard the older ages (~2.4 Myr) to be due to contamination of the feldspar separates by older material. It has also been pointed out that individual pumice blocks within

each of the reworked tuffs could conceivably be from more than one source and possibly of more than one age. Thus different ages might be obtained for a variety of analytical and geological reasons from samples collected at the one locality. K–Ar evidence of Curtis *et al.*¹¹ suggesting that tuffs mapped as the KBS in Areas 105 and 131 were of slightly different age, has now been eliminated with the discovery of a systematic error in the lower (1.6 Myr) ages²⁴.

The fission track evidence presented here has an important bearing on this discussion. There is very obvious agreement between the KBS Tuff zircon ages in Table 1 and the K–Ar ages of 1.8–1.9 Myr obtained by Curtis *et al.*¹¹, Drake *et al.*²⁴ and by McDougall *et al.*²³ which suggests that these ages date a real geological event. Also no fission track evidence was found for pumice of more than one age in the KBS Tuff from Area 131. Similarly there is no evidence that pumice from the KBS Tuff in Area 105, the type area for this tuff, has a different age from its

Fig. 4 Simplified geological map of part of Kenya showing localities of Precambrian basement rocks collected for fission track dating. Sample numbers have the prefix 7722-.

correlative in Area 131. All these observations argue against a purely geological explanation for the discrepancies in the published ages.

Table 2 clearly demonstrates the presence of detrital zircon, sphene and apatite grains in mineral concentrates separated from the pumice samples, even after very careful sample preparation. It therefore seems highly likely that feldspars separated for K-Ar dating could also contain traces of much older basement feldspar. This supports the contention that older K-Ar and ^{40}Ar - ^{39}Ar ages are the result of contamination. As discussed above the fission track ages of Hurford *et al.*¹⁴ are thought to be too old for purely analytical reasons, in particular the mis-identification of a finite number of acicular inclusions or dislocations as tracks and possibly a biased choice of grains for counting.

The presence of old detrital fission track ages also argues very strongly against the disturbance of any of the dating systems by postulated overprinting events. The pattern of ages found for detrital zircon, sphene and apatite closely matches that found in rocks of the Mozambique Belt basement which shows that the fission track ages have not been disturbed during erosion, deposition or any subsequent event. Considering the relative sensitivities of the different mineral dating systems to overprinting, it is inconceivable that total overprinting of glass and feldspar K-Ar ages at 1.8 Myr, as suggested by Fitch *et al.*¹², could have occurred without drastic effects on the detrital fission track ages, particularly those of the apatites. Thus the preservation of the old basement ages shows the hypothesis of post-depositional overprinting events to be unreasonable.

Conclusions

Redetermination of the fission track age of primary igneous zircons from pumice contained in the KBS Tuff gives a mean age of 1.87 ± 0.04 Myr. This is regarded as representing the time of eruption of the pumice which in turn is taken to be a close approximation to the time of the deposition of this tuff in the East Turkana Basin. Individual pumice blocks from the KBS Tuff in Area 131 gave ages indistinguishable from each other and from pumice in Area 105.

The external detector method of fission track dating is particularly advantageous in detecting detrital contamination and discriminating against its effects on resulting ages. Two detrital components were identified, one showing essentially concordant zircon and apatite ages and probably from a volcanic source of dominantly early Miocene age. The other has a strongly discordant pattern of apatite ages compared with sphene and zircon which matches that observed for the basement rocks of the Mozambique Belt. The preservation of these detrital mineral ages fully justifies contamination as a plausible explanation for the older K-Ar ages and is strong evidence against the existence of previously postulated overprinting events.

This work was supported by a Queen Elizabeth II Fellowship and in part by a grant from the Australian Institute of Nuclear Science and Engineering. I thank R. E. F. Leakey for his encouragement and for supporting the fieldwork, also A. J. Hurford for some zircon separates and T. E. Cerling and I. C. Findlater for valuable guidance and discussion.

Stone tools and numerous vertebrate fossils including hominids, have been found in close stratigraphic proximity to the KBS Tuff, whose age has been the subject of much debate. Concordant K-Ar ages, averaging 1.89 ± 0.01 Myr, are reported on anorthoclase phenocrysts from 13 pumice clasts collected from within the KBS Tuff or its correlatives. We believe that this age is the best estimate currently available for the time of formation of this important marker horizon within the East Turkana Basin.

PLIOCENE to Pleistocene sedimentary rocks which crop out adjacent to the eastern shores of Lake Turkana, northern Kenya, have yielded a wealth of vertebrate fossils, including hominids, and archaeological material¹⁻³. Rhyolitic tuffaceous beds within the sequence have facilitated mapping of the area¹⁻⁶, and these horizons contain samples amenable to

radiometric dating. The KBS Tuff⁴⁻⁶, within the Koobi Fora Formation, is one of these marker beds. As important hominid and artefact finds have been made within or adjacent to this stratigraphic level^{1-3,7,8}, it is of considerable importance to obtain precise and accurate ages for the KBS Tuff. Conventional K-Ar, ^{40}Ar / ^{39}Ar and fission track dating of pumice clasts within

this tuff have yielded a distressingly large range of ages⁹⁻¹⁴. In an attempt to resolve the controversy surrounding the age of the KBS Tuff we present here the results of a conventional K-Ar dating study of anorthoclase phenocrysts separated from pumice clasts found within the tuff.

KBS Tuff

Lake Turkana lies in a basin within the East African Rift System. During the late Pliocene and the Pleistocene the northeastern part of the Lake Turkana Basin was occupied by a large embayment in which sediments accumulated^{15,16} (Fig. 1). These sediments, about 325 m thick in all, are essentially flatlying, except locally, and represent a range of facies ranging from lacustrine through deltaic to fluvial.

The KBS Tuff is the topmost unit of the lower member of the Koobi Fora Formation^{4-6,15-18}, and is a medium to coarse grained vitric tuff of variable thickness, commonly about 1 m thick. Total thickness of overlying sediment does not exceed 125 m (ref. 18). In common with most tuffaceous horizons within the East Turkana sequence, the KBS Tuff is not a primary air fall tuff, but has been transported by, and deposited from, water¹⁸. Varying proportions of detrital material, derived from Miocene volcanic rocks and early Palaeozoic and Precambrian basement terrains marginal to the Lake Turkana Basin, are found within the tuffs.

Pumice clasts, up to 25 cm across, commonly water-rounded, occur locally within the KBS Tuff, and are regarded as products of the same volcanic eruptions that comprise the bulk of the tuff^{15,17,18}. The time between eruption of the primary volcanic material, including the pumice clasts and deposition within the East Turkana Basin, is considered to be very short—virtually instantaneous in terms of dating the deposits^{17,18}. Because the pumice clasts are less likely to be contaminated by detrital material compared with the enclosing tuff, most of the earlier age measurements were made on such clasts, and this is the procedure followed in this study. The clasts consist mainly of vesicular glass with variable proportions, normally less than 10% by volume, of anorthoclase phenocrysts up to 5 mm in size, and less common pyroxene. The glass is fresh to somewhat altered, and in some cases is partly replaced by carbonate. The phenocrysts are fresh and unaltered, the feldspar normally being limpid and euhedral. In the present study only the feldspar (anorthoclase) phenocrysts have been used for the dating.

Previous dating studies

Fitch and Miller⁹ dated a feldspar phenocryst concentrate, prepared from a pumice clast in the KBS Tuff, at 2.61 ± 0.26 Myr, subsequently¹² revising the age to 2.42 ± 0.01 Myr, based on results from four steps of a $^{40}\text{Ar}/^{39}\text{Ar}$ incremental heating experiment. They¹⁰ also reported $^{40}\text{Ar}/^{39}\text{Ar}$ total fusion ages on 10 feldspar concentrates from pumice clasts in the tuff, with results ranging from 0.52 ± 0.33 to 2.64 ± 0.29 Myr. In addition, conventional K-Ar ages of 8.43 ± 0.51 and 17.5 ± 0.9 Myr on feldspar from another clast (FM7054) were given¹⁰, but these old ages were thought to be caused by contamination from detrital material. Age spectra determined by the $^{40}\text{Ar}/^{39}\text{Ar}$ dating method were reported^{10,12} for feldspar concentrates from eight clasts from the KBS Tuff. Although the age spectra were stated to be complex, these authors interpreted apparent ages of 2.4–2.5 Myr for two samples (FMA274, FMA517) as crystallisation ages, and they suggested that overprinting could be recognised in most spectra at ~1.8–2.0 Myr, and in two cases at ~1.0 Myr. Support for this age of crystallisation of the pumices found within the KBS Tuff was given by Hurford *et al.*¹³, who reported fission track ages on zircon with a mean value of 2.44 ± 0.08 Myr.

Disregarding four conventional K-Ar ages on feldspar from pumice clasts in the KBS Tuff in the range 2.01–6.9 Myr, thought to be caused by detrital contamination, Curtis *et al.*¹¹ obtained concordant K-Ar ages on feldspar and glass from pumice clasts found in this horizon with mean values of 1.82 ± 0.04 Myr and 1.60 ± 0.05 Myr in two different areas, respec-

Fig. 1 Map of the Koobi Fora Region, adjacent to the northeastern shores of Lake Turkana, Kenya, showing location of the areas from which the samples for dating were obtained within the Pliocene-Pleistocene stratigraphic sequence (blank area). Volcanics forming the local basement are indicated by pattern. After Leakey and Leakey³.

tively. Subsequently, Drake *et al.*¹⁴ reported an error in potassium determinations on the samples previously dated by them¹¹ that yielded the 1.6 Myr ages. They listed¹⁴ new and revised K-Ar ages for 16 feldspar and six volcanic glasses from 13 pumice clasts in the KBS Tuff, ranging from 1.73 to 1.92 Myr, forming a reasonably concordant set with a mean of 1.8 ± 0.1 Myr.

Methods

Feldspar (anorthoclase) phenocrysts were separated from single pumice clasts found within the KBS Tuff and its correlatives in areas 105, 112 and 131, East Turkana (Fig. 1). In most cases the surface of the clasts was removed by sawing before crushing. Following crushing, anorthoclase was concentrated by a panning procedure, and normally the +1 mm fraction was retained and further crushed to $-360 + 170 \mu\text{m}$ or $-360 + 100 \mu\text{m}$. Tetra-bromoethane, adjusted to appropriate density, was used to purify the anorthoclase. The final step involved treatment of the concentrate in dilute HF (7%) ultrasonically for 5 min. Grain counting showed that the separates had a grain purity of better than 99.5%, and that glass remaining on crystal faces or as small inclusions rarely exceeded 1%.

Potassium was determined by flame photometry using Li internal standard and Na buffer on an IL 443 machine, following procedures similar to those previously described¹⁹. Argon extractions were made on aliquants of 0.9–2.9 g in a high vacuum line by radiofrequency heating. Temperatures of ~1,500°C were maintained for 30 min to ensure complete outgassing of argon from the melt. Previously it had been found²⁰ that temperatures substantially greater than that needed for fusion were required to remove all argon from K-feldspars. A tracer of ^{38}Ar , prepared from a gas pipette system, was added during the fusion. Subsequent to purification of the argon, its isotopic composition was measured in a AEI MS10 or a Micromass 12 mass spectrometer, both

operated in the static mode. Peak hopping is used on both machines and results are taken digitally on-line with a Hewlett-Packard 21MX computer, in which all data processing is done to produce an age within minutes of completion of the isotopic analysis.

Errors are quoted at the level of one standard deviation as previously described^{21,22}. The average age given in those cases where the sample was measured in duplicate has a minimum assigned error of 1%, because the uncertainties in the measurement of potassium and calibration of the ³⁸Ar tracer are of this order.

All ages are calculated using the revised ⁴⁰K decay constants and isotopic abundances, recently recommended²³. These constants yield ages 2.67% greater than those reported by most previous workers, but Drake *et al.*¹⁴ have also used the new constants.

Results and discussion

Petrographically the K-feldspar phenocrysts in the pumice clasts are homogeneous with no evidence of unmixing. Extremely fine polysynthetic twinning is observed in some crystals. X-ray diffraction measurements, using the three peak method of Wright²⁴, carried out by W. D. Birch (personal communication), indicate that the feldspar is highly disordered and structurally close to the sanidine-high albite series, exhibiting no evidence for significant unmixing or strain resulting from exsolution. The feldspar has a composition in the range Or₃₅–Or₃₉ (weight %) from X-ray diffraction analysis, comparing well with the composition of Or₃₅–Or₃₇ derived from the potassium analyses (Table 1). Following the nomenclature of Wright and Stewart²⁵ these feldspars are classified as anorthoclase.

Results of the K–Ar dating are given in Table 1. Duplicate potassium measurements agree to better than 1%, and the range of values is limited to less than 4% relative. In most cases sufficient anorthoclase was available to enable argon to be measured in duplicate; generally these agree to better than 2%.

With few exceptions, which will be discussed first, the K–Ar ages on 17 anorthoclase concentrates from 14 different pumice clasts collected from the KBS Tuff or its correlatives are remarkably concordant at ~1.9 Myr (Table 1).

Anorthoclase from sample KF43 yields anomalously old apparent ages of 4.11 and 7.46 Myr (Table 1). We attribute these poorly reproducible ages to the presence of variable but small amounts of old detrital K-feldspar in the aliquants used in the argon extractions. Careful petrographic examination of the mineral concentrate, however, did not lead to positive identification of detrital K-feldspar. Nevertheless, there is no doubt that old detrital material was being brought into the East Turkana Basin during deposition of the sediments. For example, we have obtained a K–Ar age of 456 ± 5 Myr (K = 10.73%; radiogenic ⁴⁰Ar = 9.68 × 10⁻⁹ mol g⁻¹) on a large (30 mm) crystal of microcline (sample no. 79–457) found weathering out of sediments of the Koobi Fora Formation. Such an age is typical of the Mozambique Belt of East Africa^{26,27}. Contamination of the anorthoclase concentrate from KF43 by less than 0.5% of old K-feldspar of this kind would explain the aberrant results.

Two anorthoclase separates were obtained from pumice clast 7722–109C, one from the outer part of the clast (79–19), yielding an age of 2.00 ± 0.02 Myr, and the other (79–276) from the core of the clast, giving an age of 1.89 ± 0.02 Myr. These results clearly demonstrate that the outer layers of the pumice cobbles may contain detrital feldspar.

For two pumice clasts (KF38, KF47) two size fractions of feldspar were analysed, and in each case the finer fraction yields slightly older apparent ages. For KF47 the difference in measured age for the two size fractions is barely significant, but for KF38 the ages differ by 4.5%, and this difference is regarded as highly significant. This discrepancy may be because of incomplete extraction of the argon from the coarser fraction or because of minor contamination by detrital feldspar in the finer fraction. The latter explanation is preferred but cannot be proved.

Fig. 2 K-Ar isochron diagram showing data from anorthoclase phenocrysts from pumice clasts found within the KBS Tuff. $R_1 = 293.8 \pm 2.4$; age = 1.89 ± 0.01 Myr.

Thus the K-Ar results from KF43, 79-19 and the finer fraction of KF38 are excluded from further consideration.

The average K-Ar ages for the other 14 anorthoclase separates from 13 different pumice clasts collected from the KBS Tuff, lie within the narrow range of 1.88–1.92 Myr, with a mean age of 1.89 ± 0.01 Myr (Table 1). Applying the isochron approach²¹ to these same data, yields a least squares fitted²⁸ line whose slope is equivalent to an age of 1.89 ± 0.01 Myr (Fig. 2), where the uncertainty quoted is at the 95% confidence level. Note that the line fits to within experimental error, as the value of the mean square of weighted deviates (MSWD) does not differ significantly from unity, and that the age is identical to that derived simply by averaging the K-Ar ages calculated for individual anorthoclase separates. In the isochron analysis no assumption is made concerning the $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of the non-radiogenic component. Thus the fact that the value found (293.8 ± 2.4) is indistinguishable from that of atmospheric argon (295.5) provides independent verification that in the present case the non-radiogenic argon has atmospheric composition, as normally assumed in the calculation of K-Ar ages.

The concordancy of the K-Ar results argues strongly against the presence of contamination by old detrital K-feldspar, as it would be most unlikely that the proportion of contamination would be so uniform. Because all these samples consist of clear, fresh, high-temperature, volcanic anorthoclase, which normally has excellent retention properties for radiogenic argon, the measured age is interpreted as that of the eruptive episode that produced the pumice clasts and the enclosing tuff. The KBS Tuff has never been buried deeper than about 125 m, so that temperatures since deposition are not likely to have been raised much above ambient. We conclude, therefore, that loss of radiogenic argon from the anorthoclase phenocrysts by reheating subsequent to deposition of the pumice clasts, as proposed by Fitch and Miller¹⁰, is geologically unreasonable.

On the basis of chemical data on pumices, Cerling *et al.*²⁹ have argued that the tuff in area 112 (referred to as area 105-East in their paper) is not the same horizon as the KBS Tuff in areas 105 and 131. Our results on anorthoclase phenocrysts from the pumices in the three areas show no significant differences in potassium content or in measured K-Ar age. Thus our data strongly support the view of I.C. Findlater (personal communication) that the tuff in area 112 is stratigraphically equivalent to the type KBS Tuff in area 105.

Comparison with other results

The mean K-Ar age of 1.89 ± 0.01 Myr, obtained in the present study for anorthoclase separates from 13 pumice clasts in the KBS Tuff and its correlatives, is statistically indistinguishable from the mean K-Ar age of 1.83 ± 0.06 Myr calculated from the data of Drake *et al.*¹⁴, based on 22 measurements of feldspar and glass from 13 pumice clasts in the same horizon. Nevertheless,

the spread in apparent age for the samples analysed by Drake *et al.* is significantly greater than that found in the present study. Their reported ages for glass range from 1.73 ± 0.04 to 1.90 ± 0.03 Myr (six glass fractions from four samples), and for feldspar the ages range from 1.73 ± 0.03 to 1.92 ± 0.02 Myr (16 feldspar concentrates from 13 samples), a spread of some 10%, and much greater than the quoted errors of 1–2% for individual ages. It is significant that the oldest ages reported by Drake *et al.* are in excellent agreement with those found in the present study, and that the spread is towards younger ages.

Direct comparison between the results of Drake *et al.*¹⁴ and those determined in this laboratory is possible because measurements have been made in both laboratories on three pumice clasts which were collected jointly from the KBS Tuff by T. E. Cerling and A. J. W. G., and split into two. Separates for dating were prepared independently in the two laboratories, and the results are summarised in Table 2. The differences in measured potassium content for the feldspars are small and may simply reflect slight differences in the purity of the separates. However, the differences in reported radiogenic argon content range from 5.7 to 11%, with our results higher.

Table 2 Comparison of K-Ar ages obtained on separates from the same pumice clasts in the Berkeley and Canberra Laboratories

Berkeley no.	Canberra no.	Sample	K (wt%)	Radiogenic ^{40}Ar (10^{-11} mol g $^{-1}$)	Calculated age (Myr \pm 1 s.d.)
KBS 77-109A		Feldspar	4.96	1.54	1.79 ± 0.02
	7722-109A	Feldspar	5.11	1.65	1.87 ± 0.02
		Glass	4.04	1.33	1.90 ± 0.03
KBS 77-109B		Feldspar	4.87	1.46	1.73 ± 0.03
	7722-109B	Feldspar	4.96	1.62	1.88 ± 0.02
KBS 77-109D		Feldspar	5.12	1.59	1.79 ± 0.02
	7722-109D	Feldspar	5.11	1.68	1.89 ± 0.02

Two points may be made. First, the Canberra results have a mean measured age of 1.88 ± 0.02 Myr for the three feldspars, whereas those measured in Berkeley by Drake *et al.*¹⁴ yield a mean of 1.77 ± 0.03 Myr, a difference of some 6%. Second, the age of volcanic glass from sample KBS 77-109B of 1.90 ± 0.03 Myr is concordant with the Canberra feldspar ages, but 9.8% greater than the age measured in Berkeley on feldspar from the same sample. Because glass normally is much more susceptible to loss of radiogenic argon than high temperature feldspar, it is indeed curious that the feldspar, as measured in Berkeley, yields a lower apparent age than the coexisting glass. A possible explanation for these results is that extraction of radiogenic argon from the feldspars was incomplete in the Berkeley experiments, leading to low apparent ages. We have mentioned previously the difficulty of extracting the argon quantitatively from feldspars of this kind, even when the samples have been melted in the vacuum system. Further intercomparisons are necessary to clarify this problem, but we wish to stress that overall the K-Ar age results from the two laboratories are in good agreement, and provide convincing evidence that the KBS Tuff has an age in the range 1.8–1.9 Myr.

It now seems clear that the earlier K-Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ total fusion results on feldspar from pumice clasts of the KBS Tuff reported by Fitch and Miller^{9,10}, and Fitch *et al.*¹², must be regarded as imprecise, as is evident from the large scatter of their data. This imprecision arises partly from the high atmospheric argon contamination found in most of their argon analyses, generally in the range 80–95% of the total ^{40}Ar . The meaning of the complex $^{40}\text{Ar}/^{39}\text{Ar}$ age spectra found^{9,10,12} for anorthoclase remains unclear. Three of the samples yield apparent ages for part of the age spectra between 2.4 and 2.5 Myr, possibly reflecting some detrital contamination. Fitch and Miller¹⁰ interpret apparent ages of around 1 Myr and between 1.8 and 2 Myr in some of the age spectra as indicating overprinting with loss of radiogenic argon at these times. On the basis of our data we believe the apparent ages of 1.8–2 Myr are recording the time of crystallisation and cooling of the feldspars, rather than

overprinting. It has been noted that the postulated overprinting events seem unreasonable on geological grounds. Indeed the presence of fresh glass in some of the pumice clasts, together with the relatively good agreement between the K-Ar ages on the glass and coexisting feldspar, as reported by Drake *et al.*¹⁴, provides powerful evidence against such overprinting.

Finally, the recently re-determined fission track ages, averaging 1.87 ± 0.04 Myr, on zircon separated from pumice clasts in the KBS Tuff, reported by Gleadow²⁷, are in excellent agreement with our K-Ar data, and resolve an outstanding problem.

Conclusions

The mean K-Ar age of 1.89 ± 0.01 Myr found in the present study for anorthoclase separates from 13 pumice clasts of the KBS Tuff is interpreted as the age of crystallisation and cooling of the pumices, which were deposited shortly thereafter in the East Turkana Basin. We believe that these data provide the best estimate presently available for the age of this stratigraphically important horizon within the East Turkana sedimentary

sequence. This view is reinforced by the satisfactory agreement between our results and those obtained by Drake *et al.*¹⁴ in the Berkeley laboratory on anorthoclase and glass, and the fission track ages on zircon given by Gleadow²⁷. The combined results seem to resolve the long-standing controversy surrounding the age of the KBS Tuff and indicate that this horizon was deposited in the late Pliocene as the Plio-Pleistocene boundary has an estimated age of ~ 1.6 – 1.7 Myr (ref. 30). Acceptance of such an age for the KBS Tuff also resolves the correlation problems, recently summarised by Behrensmeyer³¹ and Brown *et al.*³², between the sequences in East Turkana and the Omo area of southern Ethiopia. The present results also suggest that the KBS Tuff was deposited during the time interval represented by the Olduvai normal polarity event in the Matuyama reversed epoch of the geomagnetic polarity time scale^{33–36}.

We thank G.L.I. Isaac and R. E. F. Leakey, joint leaders of the Koobi Fora Research Project, for their encouragement. Support in the field by the Koobi Fora Research Project is gratefully acknowledged. We thank I.C. Findlater for his guidance in the field. Sample preparation and mineral separations were undertaken by M. Cowan and R. Rudowski.

Chicken lens crystallin DNA sequences show at least two δ -crystallin genes

Suraj P. Bhat, Raymond E. Jones, Margery A. Sullivan & Joram Piatigorsky

Laboratory of Molecular Genetics, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20205

Restriction analysis of chicken DNA using probes derived from a cloned cDNA and analysis of cloned genomic DNA fragments containing δ -crystallin gene sequences have indicated the presence of at least two non-allelic genes for δ -crystallin, the first and principal crystallin synthesised in the embryonic chicken lens. Electron microscopic analyses of three cloned genomic fragments revealed that the δ -crystallin mRNA gene sequences are interrupted at least 14 times in one of the δ -crystallin genes.

CRYSTALLINS are a group of structural proteins which constitute the bulk of the protein in the vertebrate lens¹. Since they are tissue specific, the crystallins are advantageous markers for cellular differentiation^{2–5}. δ -Crystallin, found only in birds and reptiles^{6–8}, is a particularly useful index of lens cell differentiation. It is the first crystallin to appear after lens induction in the chicken embryo^{9–11}. Further differentiation of lens fibre cells is correlated with a rapid accumulation of δ -crystallin mRNA^{12–14}. δ -Crystallin represents 70 to 80% of the protein synthesised by the embryonic lens fibre cells which, by 15 days of

development, contain on average $1\text{--}2 \times 10^5$ molecules of δ -crystallin mRNA per cell¹⁵. The embryonic chicken lens fibre cells synthesise much smaller amounts of α - and β -crystallin¹⁶. After hatching, δ -crystallin synthesis decreases and β -crystallin synthesis predominates¹⁶. δ -Crystallin is composed of at least two similar polypeptides^{17,18}. Although δ -crystallin mRNA has not been fractionated into more than one species^{13,19}, it is possible that the δ -crystallin polypeptides may be encoded by similar but non-identical mRNAs¹⁵.

An understanding of the regulation of δ -crystallin synthesis

during development will ultimately require knowledge of the structure of the δ -crystallin gene(s). Annealing experiments with cDNA have shown that the δ -crystallin gene sequences are situated in the non-reiterated region of the genome²⁰, but the actual number and organisation of δ -crystallin gene(s) have not been established. We have recently cloned δ -crystallin cDNA in a bacterial plasmid²¹, which provides an opportunity for analysis of the natural δ -crystallin gene(s). In this article we have used this recombinant plasmid to investigate the organisation of the δ -crystallin sequences in chicken DNA and in genomic fragments cloned from it.

Identification and cloning of δ -crystallin gene sequences

High molecular weight DNA was extracted from erythrocytes of White Leghorn chickens (gs⁻, Spafas Incorporated). The DNA was limit-digested with *Eco*RI and chromatographed on an RPC-5 column followed by agarose gel electrophoresis²². The fragments containing δ -crystallin sequences were identified by Southern blotting²³ and hybridisation to δ -crystallin ³²P-cDNA (ref. 21), synthesised from sucrose density gradient purified mRNA¹⁹. Four principal bands of DNA hybridised to the ³²P-cDNA (data not shown). Four major *Eco*RI fragments containing δ -crystallin sequences were also found with DNA isolated from pooled embryos or from adult liver or cultured embryonic fibroblasts derived from individual chickens. In these experiments nick-translated p δ Cr-2 DNA was used as a probe. p δ Cr-2 is a recombinant plasmid containing approximately 1.3 kilobases of δ -crystallin cDNA cloned in the bacterial plasmid pBR322 (ref. 21). δ -Crystallin mRNA is approximately 2 kilobases long^{19,21}. p δ Cr-2 DNA was used as a probe for all subsequent experiments.

The fragments were purified from the appropriate RPC-5 column fractions of the erythrocyte DNA by preparative agarose gel electrophoresis²⁴ and identified by analytical agarose gel electrophoresis, Southern blotting and hybridisation to ³²P-cDNA as above. We used the *in vitro* packaging method of Blattner *et al.*²⁵ to clone the two largest fragments in bacteriophage λ Charon 4A and the third largest fragment in bacteriophage λ gtWES (ref. 26). Charon 4A was selected because the lengths of the two biggest fragments were initially thought to be larger than 10 kilobases. Re-electrophoresis of the purified fragments containing δ -crystallin sequences indicated that their lengths were approximately 12, 7.5, 4 and 3 kilobases. The recombinant clones were identified by the *in situ* screening procedure²⁷. We refer to the cloned 7.5-, 12- and 4-kilobase fragments as g δ Cr-1, g δ Cr-2 and g δ Cr-3 respectively (for genomic δ -crystallin clones 1, 2 and 3).

To determine the relative orientation of the 7.5-, 12- and 4-kilobase fragments in the genome, we took advantage of an *Eco*RI site within the cloned cDNA insert in p δ Cr-2 (ref. 21). Digestion of p δ Cr-2 with *Eco*RI generates one fragment containing approximately 550 base pairs from the 3' half of the cloned δ -crystallin cDNA and another fragment containing approximately 700 base pairs from the 5' half of the cloned cDNA. The extreme 5' sequences of the δ -crystallin mRNA are not represented in p δ Cr-2. The 5' probe derived from p δ Cr-2 hybridised strongly to the cloned 7.5-kilobase fragment, extremely weakly to the 12-kilobase fragment and not at all to the 4-kilobase fragment. The 3' probe hybridised exclusively to the 12- and 4-kilobase cloned fragments. We conclude from this experiment that the 7.5-kilobase fragment contains δ -crystallin sequences located 5' to those in the 12- or 4-kilobase fragments with respect to δ -crystallin mRNA.

Visualisation of δ -crystallin sequences in the genomic clones

Electron microscopy was used to investigate the organisation of the sequences complementary to δ -crystallin mRNA within the cloned fragments. Heteroduplexes were formed between the DNAs of g δ Cr-1 and g δ Cr-2, and g δ Cr-1 and g δ Cr-3;

Fig. 1 Electron micrographs of the hybrids formed between δ -crystallin mRNA and the 7.5-kilobase fragment in g δ Cr-1, the 12-kilobase fragment in g δ Cr-2 and the 4-kilobase fragment in g δ Cr-3, respectively. Heteroduplexes were formed between g δ Cr-1 and g δ Cr-2 or g δ Cr-1 and g δ Cr-3 DNA ($10 \mu\text{g ml}^{-1}$ each) in 70% formamide, 0.1M Tris-HCl, pH 7.5, 0.15M NaCl, 0.01M EDTA and $25 \mu\text{g ml}^{-1}$ of δ -crystallin mRNA. The cloned DNAs were first kept at 85°C for 10 min and then the mRNA was added to the reaction mixture. The hybridisation was continued at 43°C for 2 h. Reaction mixtures were diluted 1:20 in the hybridisation buffer, prepared for electron microscopy²¹ and examined in a Philips 300 electron microscope. An illustrative tracing is presented for each electron micrograph. The intervening sequences (IVS) in each molecule are indicated by letters. IVS B in g δ Cr-2 was observed in only one-third of the molecules. This may be due to the short hybridised region between A and B. Alternatively, B may be a spreading artefact. It is even possible that its occasional presence is due to the existence of two different δ -crystallin mRNAs. Digestion of g δ Cr-1 by *Eco*RI released two cloned fragments of about 8.0 kilobases indicating end-to-end ligation of two fragments. This explains the viability of the 7.5-kilobase fragment in λ Charon 4A, which requires at least 10 kilobases of inserted DNA. Only one of these fragments (7.5 kilobases long) contained δ -crystallin sequences. Similarly, two cloned fragments of 5.0 kilobases and 4.0 kilobases were released when g δ Cr-3 was digested by *Eco*RI. Out of these two fragments only the 4-kilobase fragment contained δ -crystallin sequences. Arrows indicate the *Eco*RI sites: —: single-stranded DNA; --- mRNA.

δ -crystallin mRNA was then hybridised to the single-stranded region of each of the heteroduplexes. The upper panel of Fig. 1 shows an electron micrograph of a hybrid between δ -crystallin mRNA and the complementary sequences in g δ Cr-1 DNA. The RNA-DNA hybrids were interrupted by eight DNA loops, indicating discontinuity of the sequences complementary to δ -crystallin mRNA. These intervening sequences (IVS) are denoted by letters A-J; the hybridised regions are denoted by numbers 1-9 (see Fig. 2). The cumulative length of the hybri-

disised regions, which we call mRNA gene sequences (mRGS), was 1.4 ± 0.4 kilobases (mean \pm s.d.); the length of the intervening sequences was 6.2 ± 0.9 kilobases. The long RNA tail is the 3' part of δ -crystallin mRNA, since more than 60% of the mRNA sequences hybridised to g δ Cr-1, and g δ Cr-1 did not hybridise to the 3' half of the cloned δ -crystallin cDNA. The non-hybridised stretch of DNA-labelled A may be an intervening sequence because a short tail of RNA was occasionally observed to the left of mRGS 1. This suggests that a δ -crystallin mRNA gene sequence is missing from the 5' end of the 7.5-kilobase fragment. Assuming that the sequences at the extreme 5' end of δ -crystallin mRNA are not present in g δ Cr-1, IVS A would be the largest intervening sequence (at least 1.5 kilobases) in g δ Cr-1. It is interesting that the intervening sequence separating the 45-base pair leader sequence of ovalbumin mRNA in the chicken genome is 1.6 kilobases long²⁸.

The electron micrograph in Fig. 1 (middle) shows a hybrid between δ -crystallin mRNA and the single-stranded DNA in g δ Cr-2. The prominent RNA tail seen in this hybrid is the 5' end of δ -crystallin mRNA, since only the 3' half of the cloned δ -crystallin cDNA hybridises well to this fragment. The small knob-like structure present at the 3' end of the hybrid probably represents the poly(A) tail of the mRNA. Six intervening sequences (A-F) were observed in this hybrid. The cumulative length of the intervening sequences in g δ Cr-2 was 1.9 ± 0.3 kilobases and that of the mRNA gene sequences was 0.8 ± 0.2 kilobases.

The electron micrograph in Fig. 1 (lower) shows a hybrid between δ -crystallin mRNA and the single-stranded DNA in g δ Cr-3. The δ -crystallin sequences within this cloned 4-kilobase fragment hybridised only to the 3' half of the cloned cDNA probe. The long RNA tail is thus the 5' side of the δ -crystallin mRNA. Four intervening sequences (A-D) interrupted the δ -crystallin mRNA gene sequences in this cloned fragment. By analogy with g δ Cr-2, there may be a fifth intervening sequence to the left of the mRNA gene sequence 1 (see Fig. 2) in g δ Cr-3. This cannot, however, be established by electron microscopy. The cumulative length of the intervening sequences of the cloned 4-kilobase fragment is about 1.7 ± 0.3 kilobases, and that of the mRNA gene sequences is about 0.6 ± 0.1 kilobases—values in close agreement with the corresponding values for the 12-kilobase fragment. The 12- and 4-kilobase fragments thus appear to contain very similar but not identical 3' halves of separate δ -crystallin genes (see below).

Diagrammatic representations of the δ -crystallin gene sequences in the three cloned fragments are shown in Fig. 2. δ -Crystallin DNA sequences in g δ Cr-1 must be associated with those in g δ Cr-2 or g δ Cr-3 to form one of the natural δ -crystallin genes. Either combination contains a sufficient number of δ -crystallin mRNA gene sequences to account for a δ -crystallin gene, except probably the 5' leader sequence. The cumulative length of the mRNA gene sequences in the 7.5 (g δ Cr-1) and the 12 (g δ Cr-2) kilobase fragments is 2.2 ± 0.6 kilobases, and the cumulative length of these sequences in the 7.5 and the 4 (g δ Cr-3) kilobase fragments is 2.0 ± 0.5 kilobases. (δ -Crystallin mRNA is approximately 2.0 kilobases long^{19,21}.) Since the total length of g δ Cr-1 and g δ Cr-2 or g δ Cr-3 is about 10 kilobases, the intervening sequences amount to approximately 80% of the δ -crystallin gene.

The present data suggest that the two δ -crystallin genes are very similar, as judged by the pattern of intervening sequences in both 3' halves of the genes. The fact that the two 3' halves of the δ -crystallin genes are contained in a 4- and 12-kilobase fragment after *Eco*RI digestion indicates that the two genes have different flanking sequences at their 3' ends. It is possible that the 5' halves of both genes are present in the *Eco*RI fragment of approximate length 7.5 kilobases. This is consistent with the results obtained on the quantitation of hybridisation of ³²P-cDNA to different *Eco*RI fragments separated by electrophoresis after reverse-phase column chromatography. The relative amount of ³²P-cDNA hybridised to each δ -crystallin DNA band was estimated by scanning the autoradiogram. If one takes the amount of radioactivity hybridised to the 3-kilobase fragment as one unit, then the relative amounts of ³²P-cDNA hybridised to the 4-, 7.5- and 12-kilobase fragments were 2.1, 7.0 and 2.3 units, respectively. Thus, there was almost four times as much hybridisation to the 7.5-kilobase fragment as to either the 4- or 12-kilobase fragments. The remaining 3.0-kilobase fragment derived by *Eco*RI digestion of the chicken DNA hybridised much more weakly to the ³²P-cDNA, suggesting that it contains relatively few δ -crystallin mRNA gene sequences.

Further evidence for two δ -crystallin genes

In contrast to the results obtained with *Eco*RI, *Bam*HI digestion of chicken DNA gave two major fragments of approximately 8 and 10 kilobases which hybridised to nick-translated p δ Cr-2 DNA (Fig. 3). This is of interest since the cloned cDNA has a central *Eco*RI site but lacks a site for *Bam*HI²¹. Thus, the two

Fig. 2 Diagrammatic representation of intervening (IVS) and mRNA gene sequences (mRGS) in the cloned δ -crystallin gene fragments. Hybrid molecules of g δ Cr-1 DNA: δ -crystallin mRNA, g δ Cr-2: δ -crystallin mRNA, and g δ Cr-3: δ -crystallin mRNA (see Fig. 1) were measured, using a Numonics digitiser and statistically analysed. The orientation of the fragments was determined as given in the text. The arrows (\downarrow) indicate the *Eco*RI sites. The measured lengths (\pm s.d.) of IVS (letters) and mRGS (numbers) were: g δ Cr-1 (36 molecules): A, 1.60 ± 0.3 ; B, 1.30 ± 0.10 ; C, 1.10 ± 0.16 ; D, 0.40 ± 0.07 ; E, 0.30 ± 0.05 ; F, 0.39 ± 0.06 ; G, 0.32 ± 0.05 ; H, 0.35 ± 0.06 ; I, 0.23 ± 0.05 ; J, 0.19 ± 0.05 ; 1, 0.24 ± 0.09 ; 2, 0.24 ± 0.05 ; 3, 0.13 ± 0.03 ; 4, 0.09 ± 0.03 ; 5, 0.12 ± 0.02 ; 6, 0.11 ± 0.03 ; 7, 0.17 ± 0.04 ; 8, 0.07 ± 0.03 ; 9, 0.19 ± 0.06 . g δ Cr-2 (24 molecules): A, 0.67 ± 0.09 ; B, not measured; C, 0.28 ± 0.05 ; D, 0.23 ± 0.04 ; E, 0.23 ± 0.04 ; F, 0.55 ± 0.1 ; 1, 0.18 ± 0.04 ; 2, not measured; 3, 0.13 ± 0.04 ; 4, 0.10 ± 0.03 ; 5, 0.17 ± 0.03 ; 6, 0.24 ± 0.06 . g δ Cr-3 (23 molecules): A, 0.13 ± 0.03 ; B, 0.25 ± 0.06 ; C, 0.39 ± 0.06 ; D, 0.50 ± 0.13 ; 1, 0.06 ± 0.02 ; 2, 0.08 ± 0.02 ; 3, 0.10 ± 0.03 ; 4, 0.13 ± 0.03 ; 5, 0.24 ± 0.05 . —, IVS; ■, mRGS. The segment shown as a broken line in g δ Cr-3 was not visualised but may be present by analogy with g δ Cr-2.

Fig. 3 Autoradiogram of a Southern blot of *Bam*HI-digested chicken DNA after hybridisation to 32 P-labelled p δ Cr-2 DNA. DNA isolated from 6-day-old chicken embryos was digested with *Bam*HI in the buffer recommended by the manufacturers (New England Biolabs), subjected to electrophoresis in 1% agarose gel, transferred to Millipore filters²³ and hybridised⁵⁷ to different 32 P-labelled probes²¹. Each sample (20 μ g) was digested with 40 enzyme units for 12 or 24 h. Digestion with addition of fresh enzyme at 2, 4 and 6 h (final substrate:enzyme ratio 1:6) did not change the hybridisation pattern. p δ Cr-2 was cut by *Eco*RI to give two fragments 4.2 kilobases and 1.3 kilobases long containing 5' and 3' sequences of the cloned cDNA insert, respectively. These two fragments were separated by electrophoresis in a 5% polyacrylamide gel and recovered by electrophoretic elution⁵⁸, concentrated by DEAE-cellulose chromatography and ethanol precipitated. Nick translation was done with 32 P-dCTP (300 Ci mmol⁻¹) according to Maniatis *et al.*⁵⁹. Each hybridisation reaction (20 ml) contained 4–6 $\times 10^6$ c.p.m. (10^7 – 10^8 c.p.m. μ g⁻¹). T = total (uncut nick-translated p δ Cr-2 DNA).

*Bam*HI fragments were not generated by cutting in the genomic regions corresponding to the cloned cDNA sequences. Unlike the cloned *Eco*RI fragments, each of the *Bam*HI fragments contained sequences complementary to the 3' and 5' halves of the cloned cDNA probe (Fig. 3). This suggests that the *Bam*HI fragment was not produced by cutting an intervening sequence within the δ -crystallin gene. The presence of two *Bam*HI fragments is consistent with the possibility that there are two separate genes for δ -crystallin. The four *Eco*RI fragments or the two *Bam*HI fragments containing δ -crystallin sequences are apparently not derived from two structural alleles of the δ -crystallin gene, since similar restriction fragments were obtained from DNA of inbred chickens (line 6, subline 3, US Dept of Agriculture, East Lansing, Michigan) and from DNA of a parthenogenetic turkey²⁹ (data not shown).

Discussion

In this investigation we have isolated, cloned and determined the pattern of intervening sequences in three δ -crystallin gene fragments produced by *Eco*RI digestion of the chicken genome. This is the first time that gene sequences for a lens crystallin gene have been examined. δ -Crystallin gene sequences are of special interest because they are expressed principally in the embryo^{3,4,10,16} and their activity can be studied *in vivo*^{4–11} and in tissue culture^{12,15}. The present study thus provides a starting point for further analysis of the regulation of δ -crystallin gene expression at the molecular level.

Our data are consistent with the existence of at least two separate non-allelic δ -crystallin genes in chickens. The fact that

*Bam*HI DNAs digested from extensively inbred chickens and a parthenogenetic turkey have similar restriction patterns for the δ -crystallin sequences to the *Bam*HI-treated DNA from the commercially available chickens (Truslow Farms) argues against interpreting our data as evidence for two structural alleles of one δ -crystallin gene. The similarity in the restriction patterns of δ -crystallin DNA sequences in turkeys with those in chickens is consistent with the similarity in the δ -crystallin protein in these two species⁸. The two δ -crystallin genes could be adjacent with a relatively small intergenic spacer, as in the human α -globin genes^{30,31}, or they may be widely separated in the genome. The data do not exclude the presence of more than two identical δ -crystallin genes which are tandemly repeated, but previous hybridisation kinetic experiments with cDNA do not support this notion²⁰.

δ -Crystallin is composed of subunits with approximate molecular weights of 50,000 and 48,000 (ref. 17). Peptide analyses have indicated that these subunits must have very similar primary structures¹⁷; only two tryptic peptide differences have been noted between the δ -crystallin subunits³². The presence of two different genes for δ -crystallin suggests that the larger and smaller subunits of this protein may be synthesised on separate mRNAs. This would be of considerable interest with respect to the control of their translation, since it is known that the ratio of synthesis of the δ -crystallin subunits is affected by the intracellular concentration of electrolytes³³. Interestingly, the rat preproinsulin gene has recently been shown to be encoded by two similar, non-allelic genes which are equally expressed^{11,34}. However, the possible existence of two genes for δ -crystallin does not necessarily mean that each subunit is encoded by a separate gene. One subunit may be derived from the other by post-translational processing³⁵, or differential splicing of transcripts from a single gene could lead to different mRNAs^{36–38}.

The present data demonstrate that the δ -crystallin genes are highly interrupted in comparison with other eukaryotic genes^{39–49}. The chicken conalbumin gene which is interrupted 17 times⁵⁰ is the only other gene reported yet that has as many or more intervening sequences as the δ -crystallin gene. If the mRNA gene sequences are separated into functional units or domains^{51,52} the large number of intervening sequences may indicate that δ -crystallin is structurally complex. Some interesting features of δ -crystallin are that it has a greater content of leucine and isoleucine than other eukaryotic structural proteins⁵³, it has a very low proportion of aromatic amino acids⁵³, and it has a high degree of α -helical structure^{54,55}. Finally, it would be particularly interesting if the unusual abundance of intervening sequences in the δ -crystallin gene was related to its distribution among animals. δ -Crystallin is confined to birds and reptiles, as judged by immunological^{6,7} and cDNA hybridisation⁸ studies. This special distribution of δ -crystallin differs from the ubiquitous distribution of other proteins, such as actin, histones or cytochrome *c*, for example, which have uninterrupted genes⁵⁶.

We thank Ann Skalka, Shirley M. Tilghman and Marion Nau for supplying the initial high molecular weight DNA and the RPC-5 column fractions, Dr E. Buss for a parthenogenetic turkey, Jonathan G. Seidman and Philip Leder for helpful discussions and advice, Jacob V. Maizel Jr for providing facilities for the electron microscopy and Terri Broderick for typing. The recombinant DNA experiments were performed in a P3 laboratory in accordance with the NIH Guidelines.

Contribution of immunoglobulin heavy-chain variable-region genes to antibody diversity

T. H. Rabbitts, G. Matthysens* & P. H. Hamlyn

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

A mouse cloned cDNA probe containing a variable (V) region belonging to the V_HIII subgroup has been used in filter hybridisations to estimate the number of heavy-chain V-genes in this subgroup of mouse and human DNA. There seem to be about 10 and 20 V_H-genes hybridising to this probe in mouse and human DNA, respectively. Studies of cross-hybridisation of the related V_κ-genes from MOPC21 and MPC11 myelomas indicate that the experiments detect all members of the V_HIII subgroup.

THE antibody combining site comprises areas of the variable (V) regions of both heavy (H) and light (L) chains so that antibody diversity is a function of the germ-line diversity of both H- and L-chain genes combined with possible somatic modifications of these V-gene sequences. The regions of maximum variability occur in the three hypervariable regions which have been charted in the variability plots of Kabat¹. Each of the hypervariable regions occurs within or around the antigen binding site² and so each probably plays a part in the variability of antibodies. Recent studies of mouse L-chain genes have shown that the V segments in germ-line DNA are separate from the C-genes in the genome^{3–5}, and furthermore, that several J segments occur (equivalent to amino acid residues 96–108 (refs 6–8)) separated from the C_κ segment by a large intervening sequence. The integration of the immunoglobulin gene specifically involves fusion of one of a number of V segments with one of the J segments^{6–8} while the large intervening sequence is maintained^{4,7,8}. In the case of κ L-chain genes, residue 96 seems to be highly variable as a direct consequence of V–J joining^{7,8}. This residue, and thus, this event explains at least some of the variability of the third hypervariable region in κ-chains. In addition, it has been argued that variability of the first two κ-chain hypervariable regions and the remainder of the third hypervariable region are entirely encoded by germ-line genes⁹ whereas the λ L-chain seems to undergo some V-segment somatic variation¹⁰. There are no data for H-chain V-genes, and a first approach is to assess the variability of germ-line DNA by hybridisation experiments designed to detect the whole V_H-gene complement of a subgroup. Ideal probes for

such experiments are plasmid clones containing complementary DNA (cDNA) copies of immunoglobulin mRNA¹¹ which can be used in the filter hybridisation procedure of Southern¹². Thus, hybridisations can be carried out with suitable V_H probes and the number of hybridisation bands obtained can be equated with V-genes complementary to this probe. To assess the relevance of this number to the V-genes of a protein subgroup (that is, the group of V-region sequences bearing similar or identical framework (non-hypervariable region) amino acid residues), it is necessary to know the extent of V-gene cross-hybridisation in filter hybridisation experiments. In the present experiments, we have used a cloned cDNA probe of a mouse V_H sequence belonging to the V_HIII subgroup to determine the number of germ-line V_H-genes in this subgroup of mouse and human DNA. In the conditions used, we find that the probe hybridises to about 10 V_H-genes in mouse DNA and about 20 V_H-genes in human DNA. These numbers probably represent the size of the V_HIII subgroup in the respective DNAs, for by studying the cross-hybridisation of the κ V-gene sequences from MPC11 and MOPC21 mouse myelomas, we conclude that all members of the V_HIII subgroup should cross-hybridise.

Extent of V-gene cross-reaction in filter hybridisation

A characterisation of V-gene cross-hybridisation can be facilitated by comparing two V-genes of similar origin which differ in both the framework and hypervariable residues. The mouse κ-chains MPC11 and MOPC21 are suitable for such an analysis because protein sequencing of both chains^{13,14} shows that the V segments differ by approximately 20% of residues (excluding the J region and an additional region of 12 amino acids present

* Present address: Free University Brussels, Institute of Molecular Biology, 65 Paardenstraat, B-1640 St.-Genesius-Rode, Belgium.

Fig. 1 Comparison of MPC11 and MOPC21 V_{κ} sequences. The nucleotide sequence of MPC11 V_{κ} shown was derived by the chemical degradation procedure¹⁶ using the 380-base pair *Hind*II fragment derived from $p\kappa(11)^{24}$ as a source of V-region material. This fragment was labelled with ³²P (using polynucleotide kinase) redigested with *Hinf* and *Hpa*II. The resulting fragments were isolated from acrylamide gels and subsequently subjected to degradation and gel analysis²⁷. Protein sequences were taken from Svasti and Milstein¹³ and Smith¹⁴. The MPC11 κ -chain is 12 amino acids longer than MOPC21 at the N terminus of the mature protein; each peptide chain is numbered here accordingly. Therefore, the J segment, for example, extends from amino acid 108 to 120 in MPC11 and 96 to 108 in MOPC21. Where a codon differs between MOPC21 and MPC11, the full codon is given and the bases which are different within the codon are indicated by a vertical line. All other codons are identical but some ambiguities in the nucleotide data remain: we have not been able to assign convincingly bases to the third residues of MPC11 codons 70 (Val) or 75 (Thr), nor to the third residue of MOPC21 codons 41 (Gln), 47 (Leu) or 77 (Ser). hv, Hypervariable region.

at the amino terminus of the MPC11 κ -chain¹⁴). We have compared the nucleotide sequences of these V-regions and the results of this comparison are shown in Fig. 1 (note that the additional N-terminal residues of MPC11 necessitate the use of an alternative numbering system in MPC11 and MOPC21 in this figure). The sequence data contained in Fig. 1 extend from the codon corresponding to amino acid 25 of MOPC21 (residue 37 on MPC11 numbering) through the V-J junction (residues 95–96 on MOPC21 numbering) to the end of the J segment (residue 108). The nucleotide sequences were obtained by primed reverse transcriptase sequencing of MOPC21 L-chain mRNA¹⁵ or the chemical degradation sequencing methodology¹⁶ using *Hind*II restriction fragments prepared from a cDNA clone of MPC11 κ -chain [$p\kappa(11)^{24}$] (see Fig. 2) containing the MPC11 V-region¹⁷. The percentage of amino acids different in the V segment of the protein sequence compared in Fig. 1 is ~23% whereas the nucleotides differ by ~18%. This proportion of difference is representative for the V-regions as the N termini of the chains (not compared in Fig. 1) also differ by about 20% of their amino acids^{13,14}.

The distribution of nucleotide differences within the two proteins is interesting from an evolutionary point of view. The germ-line progenitors of these V-genes would seem to be derived from separate V-genes which presumably had a common evolutionary origin before V-gene duplication. The framework residues of the two genes have subsequently drifted far less than the hypervariable regions and indeed, much of this drift occurs at the nucleotide level (as manifested by silent base change) but not at the amino acid level. The hypervariable regions, on the other hand, exhibit considerable variation in both amino acid changes and silent nucleotide changes. This pattern of difference between related V-genes suggests that evolutionary pressure is exerted to change the antibody combining site (the hypervariable regions) and favours the conclusion that antibody variability in mouse κ -chain results extensively from evolutionary pressures by the creation of stable V-genes rather than by extensive somatic mutation at the level of individual antibody-producing cells¹¹.

The nucleotide comparison shown in Fig. 1 indicates the type of pattern of difference we can expect between related but different V-genes. We have, therefore, considered whether such V-genes would cross-hybridise in filter hybridisation experiments using different areas of the MPC11 V-region sequence from the cDNA plasmid $p\kappa(11)^{24}$ (Figs 3, 4). Restriction enzyme mapping and nucleotide sequencing of $p\kappa(11)^{24}$ (ref. 18) and nucleotide sequence data of the C_{κ} sequence¹⁵ yield the partial restriction map of $p\kappa(11)^{24}$ shown in Fig. 2. The enzyme *Hind*II

cleaves the $p\kappa(11)^{24}$ DNA to produce, among others, a 380-base pair fragment which extends from the codon for amino acid residue 10 (using the Smith numbering¹⁴) through the whole V-region of MPC11 to the codon for amino acid 137 within the C_{κ} -region; thus, this V fragment consists of V, J and part of the C_{κ} segment. *Mbo*II cleaves this 380-base pair V fragment twice—at the codon for amino acid 96 (Smith numbering) to yield a fragment of 260 base pairs (V-region sequences only), and at the codon for amino acid 127 to give smaller fragments of about 100 base pairs (consisting of the portion of V-region containing the third hypervariable region, the J segment plus the C_{κ} segment) and about 30 base pairs (consisting of C_{κ} only).

Figure 3 shows the hybridisation of ³²P-labelled cDNA made from MOPC21 κ -chain mRNA (made with reverse transcriptase using the specific primer T₂G₃T (ref. 19)) with *Hind*II restriction fragments of $p\kappa(11)^{24}$, the isolated intact 380-base pair *Hind*II V fragment or this V fragment cleaved by *Mbo*II. The restriction digests (see Fig. 3 legend) were fractionated on a 2% agarose gel before binding to a cellulose nitrate filter¹² for the hybridisation reaction. *Hind*II-digested $p\kappa(11)^{24}$ shows two major bands of hybridisation to the heterologous MOPC21 κ cDNA (slot b), the smaller of the two components being the 380-base pair V fragment described above. The isolated V fragment (prepared by fractionation of *Hind*II digested $p\kappa(11)^{24}$ DNA on a polyacrylamide gel followed by elution of the 380-base pair fragment) electrophoresed in slot a, shows similar

Fig. 2 Partial restriction map of the 380-base pair fragment from the MPC11 clone $p\kappa(11)^{24}$. The κ L-chain protein is depicted together with the partial restriction map of a *Hind*II fragment of $p\kappa(11)^{24}$ extending from the codon for MPC11 residue 10 to residue 137 (Smith numbering¹⁴). To relate this map to the data given in Fig. 1, the relative numbering positions of the 'conventional' (MOPC21) κ L-chain protein are written beneath the MPC11 numbering.

Fig. 3 Cross-hybridisation of MOPC21 κ -cDNA with *Mbo*II fragments of the isolated 380-base pair fragment from MPC11 $\rho\kappa(11)^{24}$. $\rho\kappa(11)^{24}$ DNA was digested to completion with *Hind*II, a portion fractionated on a 4% polyacrylamide gel and the 380-base pair fragment isolated¹⁸. An aliquot of this fragment was further digested with *Mbo*II. For the filter hybridisation, the digests of the various DNA samples were fractionated on a 2% agarose gel, and the DNA was denatured *in situ* and transferred to a sheet of cellulose nitrate¹² (Schleicher and Schüll BA-85). The filter was treated before hybridisation as described previously^{28,29} and hybridised for 48 h at 65 °C in 6×SSC containing 0.1% SDS, 0.2% Ficoll 400, 0.2% bovine serum albumin, 0.2% polyvinylpyrrolidone 360, 50 $\mu\text{g ml}^{-1}$ sonicated and denatured salmon sperm DNA plus 10 $\mu\text{g ml}^{-1}$ poly(rA) using 5×10^6 c.p.m. of ^{32}P -cDNA made on MOPC21 κ L-chain mRNA (by reverse transcriptase and T₂G₃T primer, specific activity of cDNA = 10^7 c.p.m. per μg (ref. 19)). After hybridisation, the filter was washed at 65 °C (30 min per wash) once with 6×SSC containing all the ingredients of the hybridisation except ^{32}P -cDNA, followed by five washes of 1×SSC and 0.1% SDS, after which the filter was rinsed in 2×SSC, dried and autoradiography carried out overnight using prefogged X-ray film³⁰. DNA samples fractionated on agarose and hybridised: a, isolated 380-base pair *Hind*II fragment of $\rho\kappa(11)^{24}$ (4 ng); b, complete *Hind*II digest of $\rho\kappa(11)^{24}$ (10 ng); c, *Mbo*II digest of the isolated 380-base pair *Hind*II fragment (10 ng); d, *Hae*III-digested ϕX174 DNA, labelled with ^{32}P before electrophoresis to serve as internal size standards in the DNA fractionation and transfer. kb, kilobase.

hybridisation to this region. On the other hand, the 380-base pair V fragment displayed a new, more rapidly migrating hybridisation component (260 base pairs) when cleaved with *Mbo*II. This component corresponds to the V segment of MPC11 (from which J and C_κ segments are absent) cross-hybridising to MOPC21 V-region cDNA. (The 120-base pair fragment also resulting from *Mbo*II cleavage of the 380-base pair V fragments

Fig. 4 Cross-hybridisation of MOPC21 κ -cDNA with *Hinf* and *Hpa*II digests of the isolated 3.1-kilobase *Hpa*I fragment from $\rho\kappa(11)^{24}$. $\rho\kappa(11)^{24}$ DNA was cleaved by *Hpa*I, fractionated on 0.8% agarose and the 3.1-kilobase fragment eluted from the gel⁴. Aliquots (20 ng) of this fragment (containing V, J and part of the C) were redigested with either *Hinf* (slot a) or *Hpa*II (slot b) and these digests were fractionated on a 2% agarose gel, transferred to a cellulose nitrate filter¹² and hybridised to 3×10^6 c.p.m. MOPC21 ^{32}P - κ L-chain cDNA as described in Fig. 3 legend. Sizes shown in kilobases (kb) were determined relative to unlabelled ϕX174 DNA (digested with *Hae*III) which was visualised after staining with ethidium bromide.

(which includes J and C_κ segments) does not show in the hybridisation because it was too small to bind effectively to the cellulose nitrate filter.)

Thus, the two V segments (MOPC21 and MPC11) do cross-hybridise in the conditions used for these experiments and we can, therefore, reasonably conclude that V-genes up to about 18% different at the nucleotide level will cross-hybridise. Interestingly, the MPC11 and MOPC21 V sequences from the 5' side of the *Mbo*II cleavage site (between Ala-Val position 97 (ref. 14)) contain only two substantial regions of perfect homology, one 29 bases long (Thr-86 to Leu-95) and the other 31 bases long (Val-70 to Gly-80). These areas represent the best possibilities for cross-hybridisation of the V-genes. The remainder of the sequences are broken up by base differences of various complexity. In view of this, we examined further the V-gene cross-hybridisation with segments of the V-region which exclude the homologous stretches of 29 and 31 nucleotides.

Restriction mapping of $\rho\kappa(11)^{24}$ showed the presence of sites for the restriction enzyme *Hinf* between the codons for Gly-Val at positions 69–70 and *Hpa*II between Tyr and Arg at positions 65–66 (Fig. 2). Thus, by cleaving $\rho\kappa(11)^{24}$ with either of these enzymes it is possible to generate a V segment suitable for cross-hybridisation studies which excludes the relatively long stretches of homologous sequence but includes the second hypervariable region. To simplify the analysis of the cross-hybridisation of these V segments, we prepared a subfragment of $\rho\kappa(11)^{24}$ with which to carry out the intra-V-segment

cleavage. The nucleotide sequence of the C_{κ} -region showed a cleavage site for *HpaI* at the codon for amino acid 125 (ref. 15). *HpaI* cleaves $p\kappa(11)^{24}$ at this site and at a site in the pMB9 vector to yield two large fragments of 3.7 and 3.1 kilobases. The 3.1-kilobase fragment contains the V segment together with the J and the 5' end of the C_{κ} . When this isolated 3.1-kilobase fragment is digested with *Hinf* or *HpaII*, the V segment is split into two fragments of 0.61 and 0.2 kilobases with *Hinf* cleavage and 1.1 and 0.2 kilobases with *HpaII* cleavage (unpublished data). In both cases, the 0.2-kilobase fragment is the *HpaI*-*Hinf* or *HpaI*-*HpaII* fragment containing the 5' end of the C_{κ} -region, the J plus the 3' end of the V segment (Fig. 2). The larger of the two fragments then consists of the 5' end of the V-region starting at around the second hypervariable region.

Figure 4 shows the hybridisation of purified MOPC21 L-chain cDNA with the *Hinf* or *HpaII* digests of the 3.1-kilobase *HpaI* fragment of the MPC11 clone $p\kappa(11)^{24}$. In both cases the large and small V segment-containing fragments hybridised to the MOPC21 cDNA. When the *HpaI* fragment was cleaved by *Hinf* we observed that both the 0.2- and 0.62-kilobase fragments hybridised the MOPC21 cDNA (slot a) and similarly the 0.2- and 1.1-kilobase fragments of the *HpaII* digest hybridised to the MOPC21 cDNA (slot b). Thus, again we observe that the fragment of the MPC11 clone which contains the V segment hybridised to the heterologous MOPC21 cDNA. In addition, in this case, we detect hybridisation between the V segments where no more than 18 uninterrupted base pairs can form. (For example, in the area of nucleotide sequence shown in Fig. 1, 15 homologous base pairs can form between codons for Gln-54 and Leu-58 whereas in the region where only protein sequence is known a possible 18-base pair region could exist between Ser-26 and Val-31.) The results of these cross-hybridisation experiments show that V_{κ} -genes with only short areas of homologous base sequence, interrupted extensively by mismatches, do cross-hybridise in the filter hybridisation experiments. It seems reasonable to assume that this situation will also occur with all related V-genes as the patterns of variability in general follow that shown by MPC11 and MOPC21 V_{κ} -regions. These cross-hybridisation experiments therefore set a criterion for the extent of V-gene detection and we can say that genes differing by at least 18% of their nucleotides can be detected in this type of experiment.

It must be considered, however, that the detection of cross-hybridising V segments when using cloned DNA, need not necessarily be related to such cross-hybridisations in genomic DNA. The experiments described in Figs 3 and 4 used 0.5 ng, 2 ng and 4 ng of specific hybridising sequence compared with the expected quantity of about 0.02 ng of a particular V-gene in a genomic hybridisation. This means that we are using between 25 and 200 times as much cloned V segment in these controls as

used in the genomic blots described below. This could lead to underestimates of V-gene numbers due to lower sensitivity of the latter. However, it is also true that the sensitivity of detection of the small DNA fragments described in Figs 3 and 4 is considerably weakened (compared with that of large fragments) by the relative inefficiency of binding small fragments to the cellulose nitrate filters. On balance, the relatively high quantities of the small cloned fragments are likely to mimic the situation in the genomic hybridisations.

The number of V_H -genes in mouse and human DNA

When assaying for V-genes in genomic DNA by filter hybridisation, the genes detected must represent either a group of closely related V-genes separated from the next set by at least 18% nucleotide difference, or V-genes gradually diverging in sequence from one another up to the extent of or greater than about 18% difference. Whichever of these situations exist, the results obtained for the DNA of a given species allows an assessment of the size of the inherited V-gene pool and in turn the potential requirement for somatic variation of the V-genes. We have attempted to derive information relating to V_H -gene complexity in mouse and human DNA using a mouse cDNA plasmid probe containing V_H -gene sequences. A cDNA plasmid ($p\mu/107$) has been derived from μ H-chain mRNA (of the hybrid cell line Sp1/HL (ref. 20)) and this plasmid has been shown to contain the entire V_H and C_{μ} sequences²¹. The nucleotide sequence of the 5' end of the V_H segment of $p\mu/107$ has been derived and is shown in Fig. 5 (extending from amino acid codons 1 to 38). This V_H -region (an anti-sheep red blood cell antibody) can be assigned to the mouse V_{HIII} subgroup, from which it differs by two amino acids in the first framework region from the basic V_{HIII} sequence¹ and a further four residues in the first hypervariable region (16% difference).

As shown in Fig. 5, the other two well-characterised mouse V_H subgroups [V_{HI} and V_{HV} (ref. 1)] differ extensively from the anti-sheep red blood cell Sp1/HL V_H sequence. V_{HI} differs by about 52% and V_{HV} by about 42% from mouse V_{HIII} . By considering the cross-hybridisation capabilities of V-genes analysed in the previous section, we can see that the V_H sequence in $p\mu/107$ would be expected to cross-hybridise to all V_{HIII} members because related V_{HIII} genes are likely to display the same type of variability at the nucleotide level as seen for the related V_{κ} sequences¹. The V_H -genes would be able, therefore, to cross-hybridise by virtue of relatively small regions of uninterrupted base pairing. On the other hand, comparison of the $p\mu/107$ V-region with the other subgroup sequences indicates that cross-hybridisation is unlikely because, on the basis of the sequences shown we can only find one region of potentially 15

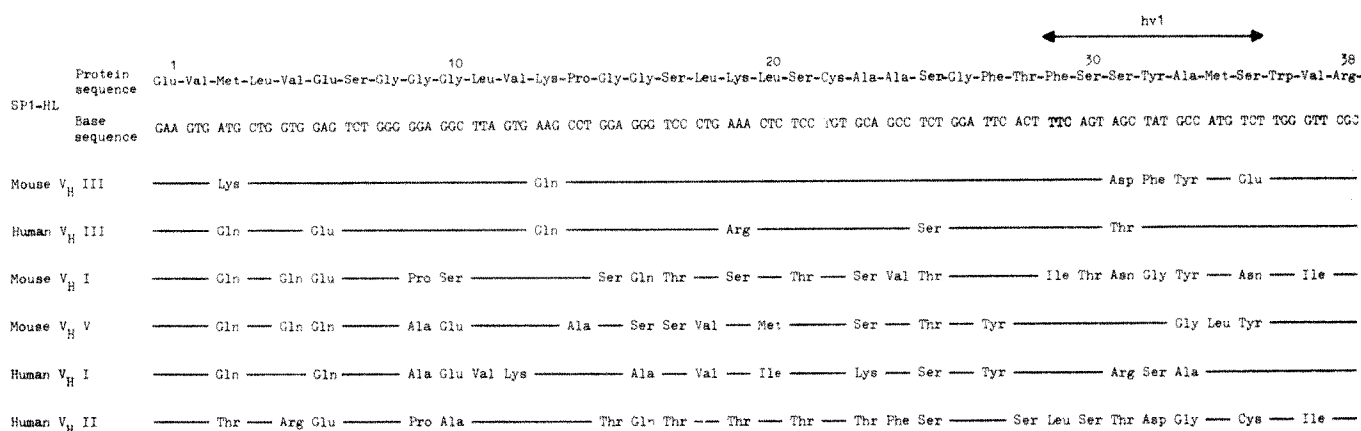

Fig. 5 Sequence of 5' terminus of the Sp1/HL heavy-chain anti-SRBC specificity and comparison with mouse and human V_H subgroups. The nucleotide sequence shown for Sp1/HL was derived by chemical degradation procedures of Maxam and Gilbert¹⁶ using an *EcoRI*-*HpaII* restriction fragment from $p\mu/107$ (ref. 21). The derived protein sequence is compared with the basic sequences of characterised mouse and human V_H subgroups¹.

homologous base pairs (in V_HV). We have also compared the Sp1/HL sequence with the human V_H subgroup basic sequences (Fig. 5). This comparison revealed that the Sp1/HL sequence is also very similar to human V_{HIII} (about 16% difference between residues 1 and 38) and, further, is more similar to the Sp1/HL sequence than the basic V_{HIII} of mouse in the area designated as the first hypervariable region. Thus, we should expect to achieve intra-subgroup cross-hybridisation between the mouse V_{HIII} probe and the human V_{HIII} genes, whereas the other human V_H subgroups differ to the extent that little cross-hybridisation would be expected (for example, there is about 39% difference between the Sp1/HL V sequence and human V_{HI} and 55% between Sp1/HL V_H and human V_{HII}).

Therefore, by carrying out filter hybridisation of mouse and human DNA with the $p\mu/107$ probe, we can estimate the V_H -gene complement for the V_{HIII} subgroup in these species. Figure 6 shows the result of filter hybridisation between ^{32}P -labelled $p\mu/107$ and fractionations of *Eco*RI-digested BALB/c mouse liver DNA (slot *a*) and *Eco*RI-digested human placental DNA (slot *b*). The hybridisation of ^{32}P -labelled $p\mu/107$ to mouse liver DNA yielded around 10 bands of hybridisation ranging from about 12.5 kilobases to about 2.7 kilobases. We have identified the largest hybridising band (12.5 kilobases) as containing the C_μ -gene so that the remaining bands represent V_H -gene hybridisation (unpublished results). In addition, it seems likely that each band represents only one hybridisation band rather than co-electrophoreses of fragments of similar size, as digests of mouse DNA with different enzymes yielded a similar number of hybridising restriction fragments. Previous studies of mouse V_κ -genes has indicated that, in general, V_κ -genes are at least 10 kilobases apart²², and our own studies on isolated V_H -genes from human DNA indicates that the average spacing of V_H -genes is greater than 10 kilobases (unpublished data). It is, therefore, a reasonable conclusion that each band contains a single V_H -gene. Thus, there are only about 10 V_H sequences in the mouse germ-line DNA which fall within the detection range of 18% nucleotide difference, and the mouse V_{HIII} subgroup therefore seems to contain only about 10 V_H -genes. Protein sequence data indicate that only four or five V_H subgroups occur in mouse¹ and assuming that they are all of a similar size, we expect about 40–50 V_H -genes in total. This number compares with the projected V_κ -gene pool size of 300 predicted from a similar type of hybridisation experiment¹¹.

Figure 6 also shows the result of hybridising the $p\mu/107$ probe to *Eco*RI-digested human placental DNA. Here we observed a more complex pattern than with mouse DNA, the hybridisation profile showing around 20 hybridisation bands ranging from about 17 kilobases to about 1 kilobase. Two of these bands hybridise to a C_μ probe¹⁸, so we are observing about 18 hybridising V_H -genes (equating each hybridising component with individual V_H -genes by analogous arguments to those for the mouse). Therefore, as we have argued that we can detect all or most V_H -genes in the human V_{HIII} subgroup, this subgroup would seem to consist of around 20 V -genes. The V_H -gene pool of human DNA would therefore seem to consist of around 80 V -genes as protein data show that there are four human V_H subgroups¹. The projected V_H -gene pool sizes calculated from the hybridisation data assume that all the protein subgroups have been discovered and that each subgroup is of approximately equal size. Discrepancies in these two parameters will, of course, introduce errors into the final value. However, study of available protein data suggests that the V_{HIII} subgroup may be a major representative of the germ-line component of V_H -genes¹.

Origin of variability of heavy-chain V-genes

The hybridisation data presented here suggest that the V_{HIII} subgroup of mouse and human DNA contains a low number of genes and that the V_H -gene pool is of the order of 40–80 genes in both species. The C_μ -gene, $C\gamma 2b$ and $C\gamma 2a$ (refs 18, 23, 26) and $C\gamma 1$ (ref. 24) genes, on the other hand, seem to represent unique components in the genome. Therefore, two clear conclusions

can be drawn. First, the V_H -gene pool must lie in the germ-line DNA separate from the C_H -gene array as in the case of the L-chains^{3–5}. Second, in order to express a V_H -gene in combination initially with the C_μ -gene, a translocation recombination event must occur to form the active H-chain gene transcription unit.

Antibody variability results from a combination of H- and L-chains and therefore the variability ultimately attained is dictated by the germ-line complement of V_H and V_L . The mouse and human V_{HIII} subgroups seem to be approximately the same size although the human subgroup is slightly larger than the corresponding group of mouse. The combination of V_H and V_κ segments in mouse could potentially generate 1.5×10^4 antibody specificities. We have no data on the V_κ complement of human DNA, but it seems likely from the available protein data that the number of κ V-genes will be smaller in human than mouse. The combination of the V_H -gene pool potential with V_κ -genes in human would, therefore, seem to be lower than the correspond-

Fig. 6 Filter hybridisation patterns of the mouse heavy-chain cDNA probe $p\mu/107$ with *Eco*RI-digested BALB/c mouse liver DNA (slot *a*) and human placental DNA (slot *b*). 15 μ g of mouse liver or human placental DNA were completely digested with *Eco*RI and fractionated on an 0.8% agarose gel alongside a mixture of *Eco*RI digest of λ phage DNA (size range 21–3.3 kilobases) and *Hae*III-digested Φ X174 (fragments visible were 1.3 and 1.0 kilobases). The positions of these markers were visualised under UV light after staining with ethidium bromide and the positions are indicated on the left hand side. After staining, the DNA was transferred to a cellulose nitrate filter¹² and the filter hybridised (as described in Fig. 3 legend) for 48 h with 25 ng ml⁻¹ ^{32}P -labelled $p\mu/107$ (labelled by nick-translation^{31,32} to a specific activity of 5×10^7 c.p.m. per μ g), followed by post-hybridisation washing and autoradiography as Fig. 3.

ing combination in mouse. This would imply that somatic variation of V segments (both V_H and V_κ) has a more important role in the generation of diversity in V segments in the human species than in the mouse. In addition, the apparently lower number of V_H -genes in mouse germ line compared with the corresponding V_κ -gene number, indicates that somatic variation of V_H -genes may be more significant than in V_κ -genes of mouse.

It is possible, however, that, particularly in mouse, the $H \times L$ combination can generate all required antibodies without significant somatic variation in the V segments. It has been postulated that the single residue 96, which is involved in the translocation joining of V_κ and J_κ , may be highly variable as a result of this joining^{7,8}, so that a somatically produced hyper-variation is believed to occur in κ -chains of mouse. It is not known whether J_H segments exist in mouse or human, although some evidence for their existence has been proposed²⁵. Therefore, the effective number of V_H -regions randomly attainable

will be the product of V_H and putative J_H segments, assuming the V and J can fuse randomly. In this respect, it is interesting that the third hypervariable ($h\nu_3$) region may be largely contained in the J_H -region, unlike the analogous region of κ -chains which does not contain much of $h\nu_3$ (refs 7, 8). Therefore, the overall number of different H-chain V-regions which can be produced will depend very much on the number of J_H segments available, as the fusion of V_H with J_H would combine the first two $h\nu$ regions with the different $h\nu_3$ regions within the J_H . In addition, the sequence of Sp1/HL V-region shows that it differs significantly from the basic V_H III sequence in both framework residues and the first hypervariable region, implying that some somatic variation may be operating on these sequences.

We thank Dr R. Perry for supplying the MPC11 clone $p\kappa(11)^{24}$. G.M. was the recipient of fellowships from the Royal Society and the National Fonds voor Wetenschappelyk Onderzoek, Belgium.

Spectrum of the Venus day sky

V. I. Moroz, Yu. M. Golovin, A. P. Ekonomov,

Space Research Institute, USSR Academy of Sciences, Moscow, USSR

The spectrum of solar radiation reflected by Venus' atmosphere has long been studied by ground-based telescopes: these studies were a major source of information on the composition of atmosphere gases and also about the upper part of the cloud layer. In December 1978 the Soviet descenders Venera 11 and Venera 12 measured the spectrum of scattered solar radiation within the atmosphere with a resolution sufficient to identify the absorption bands of atmosphere gases. We report here the first observations of the spectra of the Venus day sky.

Both vehicles landed in the equatorial region of the planet; the solar zenith angle was about 20°. The coordinates and other details of the landing area are given elsewhere¹. The results mentioned below were obtained using scanning spectrophotometers on-board the descenders. Each instrument had two measuring channels. Channel 1 recorded the spectrum of scattered solar radiation in the range 0.43–1.17 μm . The analysing element was a circular variable interference filter with a resolution of $\lambda/\Delta\lambda \approx 30$; the radiation was received from the zenith. During the station descent about 300 spectra were obtained between 62 km and the surface. Channel 2 measured the distribution of the radiation intensity in the vertical plane in four spectra regions: 0.45–0.55, 0.56–0.68, 0.9–1.14, and 1.15–1.55 μm separated by glass filters. The field of view of both channels was 20° at the 0.5 level. The instrument and its

operating conditions are described in more detail elsewhere². Figure 1 shows the spectra recorded by the Venera 11 spectrophotometer; also shown, for comparison, is the solar radiation spectrum.

The spectra at 62, 56 and 51 km were obtained inside the cloud layer. The intensities of these spectra diminish rapidly as the altitude decreases. After the vehicle emerges from the clouds (at ~49 km) the intensity varies very weakly down to 38 km and then the rapid decrease of intensity is observed as the atmosphere optical depth increases. The absorption bands of CO_2 and H_2O are seen in the spectra. The spectra measured by the two vehicles are in good agreement.

To estimate the integral flux F on the surface, the integration was made over the wavelength range 0.43–1.17 μm and over the entire upper hemisphere. It was found that $F = 72 \text{ W m}^{-2}$, which is ~3% of the solar radiation flux outside the atmosphere. The surface illuminance is about 9,000 lx, which is in good agreement with the results from Venera 9 and Venera 10 (ref. 3). According to the spectrum obtained, the colour of the surface is orange.

Figure 2 gives the height dependence of radiation intensities from the zenith for $\lambda = 0.45, 0.5, 0.635, 0.72$ and $1.0 \mu\text{m}$. The part of the curve for $\lambda = 0.5 \mu\text{m}$ is shown on a larger scale, together with experimental points. Examination of the curves shows three sublayers with different extinction coefficients: a 49–52 km sublayer is the most dense optically, 52–58 km is the most transparent and 58–62 km forms a layer with an intermediate optical density. Nearly the same stratification was found in the optical experiments on Pioneer Venus^{4–6}.

Estimates of the multiple light scattering were used to analyse the data. In one of the analyses the atmosphere was divided into 20 layers, intensities were calculated by the adding method⁷. The reflection and transmission of each layer were determined

by a two-flux approximation. The profiles of intensity, close to those measured in the continuous spectrum, were estimated using the variations layer model parameters. The following model was constructed from these results. (1) The main cloud layer is at 49–68 km, its full optical depth is $25 < \tau < 35$ in a spectral region of $0.63 < \lambda < 1.00 \mu\text{m}$; (2) the optical depth of the lower most dense part of the main cloud layer (49–52 km) is about 12; (3) the single scattering cloud particles albedo is $0.998 < a < 1.000$; (4) at 49–32 km there is very weak aerosol haze with an optical depth of about 0.7 below the main cloud layer. Optical depth has been estimated using the assumption that the scattering is anisotropic and Henyey–Greenstein phase function parameter is $g = 0.7$ (this corresponds to size of particles $\sim 1 \mu\text{m}$).

The above mentioned characteristics of the cloud layer, together with the data on the Rayleigh scattering and the absorption coefficients of H_2O and CO_2 , were used to calculate synthetic spectra in the region of the absorption bands. Comparison of synthetic and measured spectra yields a preliminary conclusion that the mixing ratio is $[\text{H}_2\text{O}]/[\text{CO}_2] \approx 2 \times 10^{-5}$ near the surface but that it gradually increases and in the clouds it is $[\text{H}_2\text{O}]/[\text{CO}_2] \approx 2 \times 10^{-4}$. The last evaluation is close to the results obtained on Venera 9 and Venera 10 (ref. 8). Both estimates strongly contradict the published results of measurements of the gas chromatograph on Pioneer Venus⁹, which give the abundance of H_2O from 0.1 to 0.5%. The gas chromatograph on Venera 12 gave the upper limit of $\text{H}_2\text{O} < 10^{-4}$ for heights under 42 km that agrees with our estimates. The decrease of H_2O mixing ratio between the clouds and the surface may be associated with some processes of chemical binding of H_2O in rocks¹¹.

The depression in the blue part of the measured spectrum (heights under 30 km, Fig. 1) can be only partially explained by the Rayleigh scattering. Sulphur in the gaseous phase (S_2) can absorb in this region and in this case the mixing ratio of $[\text{S}_2]/[\text{CO}_2]$ is $\sim 10^{-8}$. In any case this value can be considered as an approximate upper limit. There may possibly be a contribution from absorption of other molecules here, such as Cl_2 , Br_2 and NO_2 . The corresponding upper limits are approximately 10^{-8} , 10^{-10} and 5×10^{-10} . The sensitivity of the optical spectroscopy for some substances (even for low resolutions) in the Venus low atmosphere turns out to be higher than for the mass

Fig. 1 Samples of spectra of scattered solar radiation obtained by Venera 11. Numbers near the curves are heights above the surface.

Fig. 2 Zenith intensity of the radiation as a height function for some wavelengths. E_\odot is the solar illuminance at the upper boundary of the Venus atmosphere. Numbers near the curves are the wavelengths.

spectrometer and the gas chromatograph. There is an indication that the concentration of the substance absorbing in the blue might decrease near the surface. In the altitude range 0–7 km the height dependence of intensity (in the blue) can be explained by assuming that there is only the Rayleigh scattering in this region of the atmosphere; the absorption appears only at higher altitudes. This absorption practically disappears again above 30 km. There is also some blue absorption in the top part of cloud. This cloud absorption, taking the assumption¹² into account, is caused by condensed sulphur.

More detailed reports on the above analysis of the spectra obtained on Venera 11 and Venera 12 probes are given elsewhere^{2,13,14}.

Discovery of frequent lightning discharges in clouds on Venus

L. V. Ksanfomaliti

Space Research Institute, Profsoyuznaja, 84, 117810 Moscow, USSR

The analysis of the composition of the Venus atmosphere made by seven Soviet Venera-type spacecraft between 1967 and 1975 has resulted in speculation about the possible role of lightning in the formation of some minor atmospheric components similar to the Earth's atmosphere. The glowing of the Venus nightside, the ashen light, sometimes observed¹ might also be explained by lightning in the Venus atmosphere. Calculations show, however, that there must be many lightning discharges to be visible from the Earth. Nevertheless, although some speculation has arisen about the existence of lightning in the atmospheres of the other planets until recently only lightning discharges in the Earth atmosphere were known.

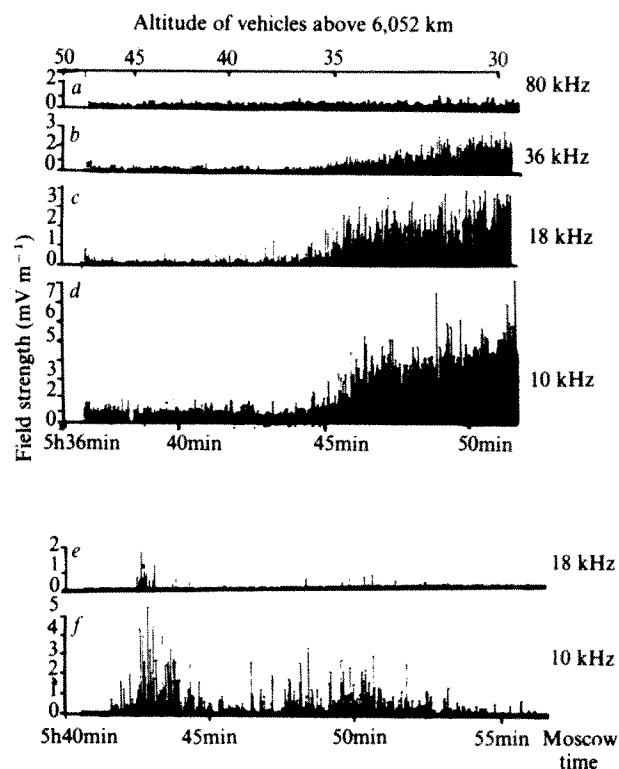

Fig. 1 Comparison of the electric thunderstorm activity of the Venus atmosphere during the Venera 12 descent (*e, f*, 21 December 1978) and the Venera 11 descent (*a-d*, 25 December 1978). The altitude scale refers to both vehicles. The signal was recorded in the bands: 1.6, 2.6, 4.6 and 15 kHz at frequencies: 10, 18, 36 and 80 kHz, respectively.

The GROZA experiment was carried out on board the Venera 11 and Venera 12 spacecraft in December 1978 to search for lightning in the Venus atmosphere². (Hara³ has developed the same idea independently, while our experiment was under preparation.) The GROZA instrument recorded impulses of the electromagnetic radiation produced by the lightning discharges. It consists of a radio receiver/spectroanalyser covering a range of 8 to 90 kHz and an impulse counter of discharge rate. The instrument had an external magnetic loop antenna operating at temperatures up to 500 °C and pressures up to 100 bar. The instrument worked both during its descent and on the planetary surface.

The following points were considered during preparation of the experiment. The intensive motions in the planetary cloud layer⁴ at heights 50–70 km were expected to contribute greatly to the accumulation of rather strong electrical charges in

Fig. 2 The unique group of impulses recorded on the planetary surface by Venera 12, 30 min after the landing.

clouds⁵. The large altitude of the lower boundary of the cloud layer means that the discharge to the surface would require enormous potentials. 'Cloud-cloud' discharges, well known in case of the Earth are more probable. The discharges of Earth lightning are characterised by high energies of $\sim 10^9$ J. Thus, energy is determined by the conditions in which electrical discharges occur in a gas: the energy an electron obtained during its mean free path has to exceed the gas ionisation potential (that is, of 13.8 eV for CO₂ and somewhat less for air). To satisfy this condition the electric field must reach some hundreds of kV m^{-1} . Therefore, the charges accumulating in the atmosphere reach tens of coulombs⁶. The lightning is followed by the transport of a very significant charge, equal to about several coulombs, that produces the high energies of lightnings. As for aerosols their conductivity affects discharge only slightly. Hence if there is an accumulation of charges in clouds on Venus the lightning energy must be of the same order as that on the Earth.

Fig. 3 Periodic sequence of the radionoise bursts recorded by the Venera 11 at heights 13–10 km. The source was the thunderstorm region with the lateral extent of ~ 150 km at $\sim 1,500$ km from the landing site.

The space vehicles had almost the same descending trajectory, and the descent operation was carried out in the same equatorial region of Venus⁷. During the descent a thousand impulses were recorded that were similar to the radiation of lightning in distant thunderstorms on Earth but with a high rate of discharge. While the Venera 11 was descending, the thunderstorm events were rather intense (on 25 December 1978) but during the descent of the Venera 12 (on 21 December 1978) there were fewer discharges. The solar activity during the latter half of December was very low and comparatively constant. The difference in the character of these events probably relates to the local nature of Venus thunderstorms. The discharge rate was 20–30 s^{-1} and in some cases reached up to 50 s^{-1} . The comparison of the records made at heights of 30–50 km for both vehicles is shown in Fig. 1: *e, f*, Venera 12; and *a-d*, Venera 11. The field strength reaches 300 $\mu\text{V m}^{-1} \text{Hz}^{-1/2}$ at 10 kHz. The

decrease of the strength with a frequency is close to f^{-1} on average. Due to the small time constant of the spectral bands (0.24 s) and the compressed character of the curves, each impulse record is in the form of vertical bars. Venera 11 recorded impulses continuously; five different sources (or events) can apparently be singled out. On the planetary surface the GROZA counters recorded during 110 min only one group of 160 impulses received for 8 s. Due to the sampling frequency (3 s^{-1}) the field strength at the 10 and 18 kHz bands resembled that shown in Fig. 2.

The sequence of impulses with noticeable periodicity associated with both the vehicle slow rotation and the directional pattern of the GROZA antenna turned out to be a key for determining some characteristics of venusian thunderstorms (Fig. 3). The sequence consists of six periods of great bursts with some hundreds of impulses in each. Calculations² showed that the signal was emitted by the source with small angular size of $\sim 5^\circ$. The field strength showed that the source was $\sim 1,500 \text{ km}$ away and had a lateral extent of about 150 km (it was assumed that the source strength in Venus clouds was similar to that in terrestrial clouds). Probably the source was a part of the cloud layer. There were about 25 lightnings per second in this source: this burst took place on the radio horizon and for the next few minutes the source should be behind the radio horizon—a fact which should have been confirmed by Fig. 3. However, more precise calculations using the diffraction theory showed that the radio occultation should have lasted for many minutes in spite of the rapid descent of the vehicle; therefore, it is difficult to explain the sudden cutoff of the signal at 6 h 11 min. Perhaps there are peculiarities in the wave propagation, typical of Venus, that we don't know about, as the field strength from other radio sources also decreases very quickly for 2–3 min.

From 8 km above the surface until they landed both vehicles recorded the many impulses having moderate amplitudes which decreased up to the same level as the radionoise near the surface (Fig. 4). This is the only event seen at the same altitude on the records of both 21 December and 25 December. In Fig. 4 the

Fig. 4 Bursts recorded by the Venera 11 before the landing. It covers the altitudes 8–2 km. Immediately before the landing and on the surface the level of atmospheric radionoise was very low. The burst shows most prominence at 36 kHz.

group of impulses with distinct frequency properties can be singled out: from 6 h 11 min to 6 h 14 min the field strength was $50 \mu\text{V m}^{-1} \text{ Hz}^{-1/2}$ only in the range 33–38 kHz whereas at frequencies 10 and 18 kHz the field strength was only 10–20 $\mu\text{V m}^{-1} \text{ Hz}^{-1/2}$ —this event also remains obscure.

From the beginning of January 1979 the Pioneer Venus orbiter began recording low-frequency impulses of electromagnetic radiation at periastron which Taylor *et al.* also identified with the lightning radiation⁸. So, these observations appear to confirm our interpretation. The high lightning rate on Venus apparently makes it possible to explain its glowing on the nightside. Calculation shows that for the phase angle of 90° (when the half of the planet is illuminated) the light flow from the nightside can be 10^{-4} of the reflected sunlight if the thunderstorm activity covers 4–38% of the planetary surface depending on the efficiency of the transformation of lightning energy into light⁹.

Intensive and frequent discharges of lightning (up to 50 s^{-1} in one active region) occur in the Venus cloud layer. The origin of some gaseous components of the atmosphere can be associated with this lightning. During the Venera 11 and Venera 12 investigations the thunderstorms were of a local nature. The high lightning activity on Venus can explain the nightside glowing observed from the Earth. Lightning phenomena are, therefore, typical of the Earth and also of other planets with rather dense atmospheres and clouds where the conditions necessary for great charges to accumulate are realised.

Is something wrong with the binary pulsar?

W. Kundt

Institut für Astrophysik der Universität Auf dem Hügel 71,
D-5300 Bonn, FRG

The binary pulsar PSR1913+16 is at present the most interesting object for measuring general relativistic effects¹ such as the periastron advance, emission of gravitational waves, and gravitational redshift. It also offers unique possibilities for studying the properties of one or two neutron stars. Yet several of the observed effects could be simulated by an extended secondary, and recent optical measurements^{2,3} have suggested that such is the case, at the 97% confidence level. Here I shall argue that the optical source seen at the position of PSR1913+16 may be the pulsar sphere, that is, a region of confined extremely relativistic plasma glowing in the near IR, and that the secondary is another neutron star (as preferred by most authors). Therefore, the optical coincidence need not cause us to doubt the published general relativistic analysis of this system. I shall also comment on the binary pulsar's likely history, and on the possible presence of a second binary pulsar in Cas A.

At its present spindown rate¹ of $\dot{P} = 0.864 \times 10^{-17}$ and period $P = 0.0590 \text{ s}$, the binary pulsar loses rotational energy at a rate

$$-\dot{E} = -I\Omega\dot{\Omega} = 10^{33} I_{44.8} \text{ erg s}^{-1} \quad (1)$$

where $\Omega := 2\pi/P$. I is the moment of inertia, and

$I_{44.8} := I/10^{44.8} \text{ g cm}^2$ equals unity for the Crab pulsar⁴. Where does this power go?

In the case of the Crab, the pulsar is thought⁵ to illuminate the surrounding supernova remnant; that is, a substantial fraction of its rotational energy losses is thought to be converted into magnetobremstrahlung of the Crab nebula. More quantitatively⁴, half of the corresponding power may be pumped into the 30-Hz wave bath, and post-accelerate the expanding filaments as well as heat the lowest-energy relativistic electrons. The other half of that power is thought to be injected into the nebula in the form of highly relativistic electrons and positrons, with Lorentz factors γ in the range $3 \times 10^5 \leq \gamma \leq 10^7$, distributed according to $N_\gamma d\gamma \sim \gamma^{-2.2} d\gamma$. In the nebular electromagnetic field of strength $\leq 10^{-3}$ G, these particles lose their energy via magnetobremstrahlung whose power peaks at the frequency

$$\nu_B = eB_\perp \gamma^2 / \pi m_e c = 6 \times 10^{15} \text{ Hz } B_{-3} \gamma_6^2 \quad (2)$$

that is, in the UV.

If the Vela pulsar has the same moment of inertia as the Crab pulsar, some 10% of its spindown power escape as pulsed γ rays^{6,7}, between 0.3 and 3 GeV. Luminosities at radio frequencies⁸ and X-ray energies⁹ are about 10 times smaller than at γ -ray energies. In analogy to the Crab, more than half of the spindown power is expected to be converted into magnetobremstrahlung (= synchrotron, or synchro-Compton radiation), probably at IR frequencies. Because of the large angular extent of the source, such a flux is difficult to measure. The magnetic fields in Vela X may be of the order⁹ of $10^{-4.5 \pm 0.5}$ G, so that the observed parts of the spectrum and equation (2) imply injected Lorentz factors in the interval $10^5 \leq \gamma \leq 10^8$.

The binary pulsar has a period between those of the Crab and Vela pulsars, and an inferred surface field strength

$$B_s = (3c^3 |\dot{E}| / 2R^6 \Omega^4)^{1/2} = 1.8 \times 10^{10} \text{ G} \quad (3)$$

which is more than 10^2 times weaker. Here a standard neutron star radius $R = 10$ km has been assumed, and a perpendicular magnetic dipole field responsible for the radio pulses. The binary pulsar's spindown age, $t = P/2\dot{P} = 1.1 \times 10^8$ yr may be an overestimate of its true age; but t is certainly a measure of the pulsar's present ageing rate or lifetime. If it were a large overestimate of its true age, by a factor N , we should expect, on statistical grounds, to see N more binary pulsars in the sky.

As supernova remnants containing pulsars (not shrouded neutron stars) seem to disperse within little more than 10^4 yr, the binary pulsar will presently find itself surrounded by typical interstellar matter, with a static pressure $p_{\text{stat}} \leq 10^{-12} \text{ dyn cm}^{-2}$, and a hydrogen density $n = T_4^{-1} \text{ cm}^{-3}$. Its relativistic wind will be confined by this matter, and run into an inner shock at a distance r_i where the wind pressure $|\dot{E}|/4\pi r_i^2 c$ meets the cavity pressure p_{cav} . In a steady-state flow, p_{cav} equals the ram pressure

$$\rho v^2 / 2 \leq 10^{-9} n_0 v_{7.5}^2 \text{ dyn cm}^{-2} \quad (4)$$

of the ambient medium, where $v = 10^{7.5} \text{ cm s}^{-1}$ is the assumed relative velocity brought about by two successive supernova explosions, see equation (8), and the inner cavity radius is

$$r_i = (|\dot{E}|/4\pi c p_{\text{cav}})^{1/2} \geq 2 \times 10^{15} p_{-9}^{-1/2} \text{ cm} \quad (5)$$

The cavity must have a larger transverse than longitudinal extent for a large pressure anisotropy $p_{\text{ram}}/p_{\text{stat}} \gg 1$ of the confining surroundings. Its size is controlled by the condition that the pulsar's particle supply must leave through its outer edge at a speed v_{esc} typical for the (much heavier) ambient medium, which implies $r_0/r_i \approx (c/v_{\text{esc}})^{1/2} \leq 30$ for the outer radial scale r_0 , or

$$r_0 \leq 10^{17} p_{-9}^{-1/2} \text{ cm} \quad (6)$$

The magnetic field inside the cavity will at least reach pressure balance strength $B = 2 \times 10^{-4} p_{-9}^{-1/2} \text{ G}$. This value is even likely to be a large underestimate because the cavity boundary is strongly Rayleigh-Taylor unstable, and intruding filaments of interstellar matter will be wrapped into much stronger magnetic fields¹⁰, reminiscent of the magnetic knots in Cas A. The extremely relativistic electrons traversing the cavity have a synchrotron lifetime

$$t_{\text{syn}} \approx (m_e^5 c^9 / e^7 B^3 \nu)^{1/2} = 0.8 \times 10^3 \text{ yr } B_{-3.5}^{-3/2} \nu_{14}^{-1/2} \quad (7)$$

if radiating at the frequency ν in a field of $10^{-3.5}$ G. At a typical gyrocentre speed of $10^{7.5} \text{ cm s}^{-1}$, they therefore lose a significant fraction of their energy over a distance of several 10^{17} cm $B_{-3.5}^{-3/2} \nu_{14}^{-1/2}$. For an effective cavity radius of 10^{17} cm , particles may traverse some $3 \times 10^{17} \text{ cm}$ before they leave the vicinity of the pulsar, and are dragged along by the wake into regions of reduced pressure and much lower synchrotron brightness. Consequently, from a distance of $d = 5$ kpc the pulsar sphere is expected to look like a source of angular diameter ≤ 2.8 arc s $d_{22.2}^{-1} p_{-9}^{-1/2}$, whilst the reported 'star' has an unresolved size of ≤ 2 arc s in the deep red band³. (See also ref. 11 which excludes pulsations at the 1% level.) I propose that the reported star is in fact the glowing pulsar sphere.

This interpretation is strengthened by the fact that from the observations by Kristian *et al.*² and Crane *et al.*³ one can derive an $R - V$ spectral index $\alpha = -2.6$, ($S_\nu \sim \nu^\alpha$), very unlike that of a hot star; of course, α carries a large uncertainty. The detected flux of $1.6 \times 10^{-5} \text{ Jy}$ at $0.68 \times 10^{-4} \text{ cm}$ corresponds to an R -luminosity of $L_R = 2 \times 10^{32} \text{ erg s}^{-1} = 0.2 |\dot{E}_{\text{PSR}}|$, in agreement with the model. Note that an additional power input of $\pi r_0^2 \rho v^3 / 2 = 5 \times 10^{30} \text{ erg s}^{-1} r_{17}^2 v_{7.5}^3$ is expected from the ram pressure exerted against the interstellar medium, with voltages of the order of $2 r_0 e B_\infty v / c = 10^{12} \text{ eV } B_{-5} v_{7.5}$. This power is, however, small unless v exceeded 10^3 km s^{-1} .

The proposed identification of the binary pulsar's sphere with the starlike optical source near $(l, b) = (49.97^\circ, 2.1^\circ)$ is based on an assumed distance ≥ 5 kpc corresponding to the dispersion measure $171.64 \text{ pc cm}^{-3}$. If the pulsar's rays crossed (E. Schröder, personal communication) the Strömgren sphere of the star at $(l, b) = (49.6^\circ, 0.25^\circ)$ which has been tentatively classified as OV, the dispersion measure could be a large overestimate of distance, and the binary pulsar could be as near as 0.8 kpc. In view of the small observed variability (L. A. Fowler, personal communication) of the dispersion measure [$< 0.6 \times 10^{-4}$], however, this possibility is not very likely.

Are the binary pulsar's properties exceptional? Its low inferred surface field strength (equation (3)) has sometimes led to the conjecture¹² that it is the older of the two hypothetical neutron stars, and that it was born with a much higher magnetic field. There is, however, as yet no conclusive evidence that neutron star magnetic fields do decay on a time scale of 10^8 yr; see refs 13–15. If pulsar dipole fields did decay, they would have to do so with a rather wide range of decay times, between $\sim 10^7$ and 10^{10} yr. (But magnetic field decay may have taken place in the—probably $\sim 10^{10}$ yr old—X-ray bursters¹⁶.) But there is significant evidence that binary neutron stars are spun down by the wind of their companion star^{17,18} to periods which are in most cases too long to make them visible as pulsars. The older of the two neutron stars may hence be spinning too slowly to be detected. Why then does the younger neutron star lack a strong magnetic field?

The possible evolutionary histories of the binary pulsar have been carefully discussed elsewhere^{12,19,20}. In view of the more recent data, the most convincing configuration before the last supernova explosion in the system is a neutron star in close circular orbit around a He star. One can then calculate the presupernova parameters of the system under the idealising assumptions of: (1) an initially circular relative orbit; (2) an instantaneous and symmetrical explosion; and (3) vanishing momentum transfer to the companion during the explosion. The condition of coincident initial conditions at periastron yields¹²

$$\begin{aligned} (M_1^- - M_1)/M &= \epsilon = 0.617 \\ M_1^- &= M_1 + \epsilon(M_1 + M_2) = 3.0 M_\odot \\ a^- &= (1 - \epsilon)a = 0.747 \times 10^{11} \text{ cm} \quad (8) \\ \omega^- &= [(1 + \epsilon)/(1 - \epsilon)^3]^{1/2} \omega = 2\pi/1.44 \text{ h} \\ v_{\text{rec}} &= \epsilon(1 - \epsilon^2)^{-1/2} (M_2/M)(GM/a)^{1/2} \\ &= 1.8 \times 10^7 \text{ cm s}^{-1} \end{aligned}$$

where superscript ‘-’ denotes presupernova values, ε = numerical eccentricity, a = semi-major axis, ω = orbital angular velocity, v_{rec} = recoil velocity, and $M_1 = (1.3 \pm 0.15) M_{\odot}$, $M_2 = (1.5 \pm 0.15) M_{\odot}$ are the best estimates at present (L. A. Fowler, personal communication) for the masses, with $M := M_1 + M_2 = 2.83 M_{\odot}$. Obviously, the system could not get disrupted in the explosion because there was not enough mass in the shell. The ‘missing mass’ in the shell may have been evaporated by the closely orbiting (first) neutron star¹². Hence an exceptional property of the binary pulsar (when compared with other pulsars) is the small separation of its progenitor system, which in turn may have resulted from an exceptionally small mass ratio of the massive binary from which it descended²¹.

I shall now argue that a close presupernova orbit is likely to imply a small magnetic dipole moment of the resulting neutron star, and may hence be the only exceptional property of the binary pulsar. The argument follows Ruderman and Sutherland²² in that the neutron star inherits its magnetic moment from the convective core of its progenitor star, whose equipartition magnetic flux decreases with decreasing convective motion and hence with decreasing spin. But a presupernova binary separation of one solar radius gives rise to such a strong tidal couple that near-synchronous rotation is enforced within²³

$$\tau_1^{\text{synch}} \approx \frac{\alpha}{K} \left(\frac{M_1}{M_2} \right)^3 \left(\frac{a}{R_1} \right)^9 \frac{1}{\omega} \approx 10^{-2} \text{yr} \left(\frac{a}{R_1} \right)^9, \quad (9)$$

where $\alpha/K \approx 8$, and R_1 is the radius of the helium star (through atmosphere of which the neutron star orbits). A spin period of the core of more than 1 h is still short enough to give rise to a fast pulsar, but probably not fast enough to drive a strong dynamo²².

Why may the older of the two neutron stars have a higher mass? It is tempting to speculate that it has accreted some $0.1 M_{\odot}$ throughout several Myr from the atmosphere of its companion.

The binary pulsar, therefore, (still) allows us to think of neutron stars as objects with standard properties produced by ideal supernovae. All that may be special about it is the small separation of its progenitors, which prevents disruption, implies a small magnetic moment, a low luminosity, and high space velocity (imparted both by the first and second supernova explosion).

An even larger space velocity must have been imparted to the (light) supernova shell blown off when the binary pulsar was born (due to momentum conservation). As I have argued previously¹⁰, a light supernova shell [$< 3 M_{\odot}$] with a high space velocity [of $(165 \pm 15) \text{km s}^{-1}$] is Cas A. Cas A is exceptional for its radio brightness: Tammann²⁴ estimates that at most 2% of all supernova remnants are similar to it. Its recoil partner should presently be located at (23 h 21 min $(12 \pm 0.5) \text{s}$, $58^\circ 32' (17 \pm 1)''$). As no (strong) pulsar nor bright star has been found in this region, a (weak) binary pulsar is a likely candidate. It could, perhaps, be the third²⁵ binary system in which emission of gravitational waves is measurable.

I thank B. Eckart for discussions, and N. Holloway for the manuscript.

Magnetic energy conversion, magnetospheric substorms and solar flares

S.-I. Akasofu

Geophysical Institute, University of Alaska, Fairbanks, Alaska 99701

An explosive conversion of magnetic energy has long been suggested as the cause of various electrodynamic processes in astrophysical conditions, such as auroral magnetospheric substorms, solar flares, stellar flares and some galactic scale processes^{1–6}. It is generally believed that the magnetic energy is stored in a certain region before the onset of those phenomena and that the conversion takes place spontaneously or by triggering. Here it is suggested that the magnetospheric substorm is a direct consequence of increasing power generated by the solar wind–magnetosphere dynamo, rather than of a hypothetical sudden conversion of the stored magnetic energy.

The magnetospheric substorm has been thought to be the manifestation of a sudden conversion of the magnetic energy stored in the magnetotail before substorm onset. It has been believed that solar flares arise from an explosive conversion of the magnetic energy stored in the coronal level above a large sunspot group. Among these and stellar situations, the magnetosphere is the only region which can be ‘diagnosed’ systematically by *in situ* measurements of plasma quantities, as well as of electric and magnetic fields, providing the grounds to test the hypothesis of a sudden magnetic energy conversion. The solar wind (a magnetised plasma flow) and the magnetosphere (a magnetised celestial body) constitute a dynamo. The dynamo-induced current flows in various parts of the magnetosphere, including the magnetotail and the ionosphere. Therefore, by comparing time variations of the input energy flow into the magnetosphere, the amount of the magnetic energy in the magnetotail and the energy consumed by the magnetosphere, one should be able to identify what processes are involved in magnetospheric substorms.

We have recently found a particular solar wind quantity ε which correlates well with the rate of the total energy \dot{U} consumed by the magnetosphere⁷. It is given by:

$$\varepsilon = VB^2 \sin^2 \left(\frac{\theta}{2} \right) l_0^2 \quad (1)$$

where V (cm s^{-1}) is the solar wind speed; B (G) is the magnitude of the interplanetary magnetic field; θ is the polar angle of the IMF projected onto a plane perpendicular to the Sun–Earth line; l_0 is constant ($= 7R_E$); and \dot{U} is the sum of the rate of the Joule heat production in the ionosphere \dot{U}_i , the rate of the ring current particle in injection \dot{U}_R , and the rate of auroral particle injection \dot{U}_A .

Furthermore, it has been shown⁸ that ε is equal to the power P generated by the solar wind–magnetosphere dynamo, which is given by⁹

$$P = \frac{1}{4\pi} (B_{\text{tan}} B_{\text{norm}}) VS \quad (2)$$

where B_{tan} and B_{norm} denote the tangential and normal components of the magnetic field at the magnetopause and S denotes the surface area of the magnetotail.

It is thus of great interest to examine the relationship among the solar wind–magnetosphere energy coupling function (ε), the

Fig. 1 Comparison of the solar wind-magnetosphere energy coupling function ϵ , the magnetic energy density $B_T^2/8\pi$ in the high latitude lobe in the magnetotail, and the magnetospheric substorm index AE . These data were obtained at Explorer 35 and 34 satellites and auroral zone stations, respectively, and their locations with respect to the magnetosphere are shown in the insert.

magnetic energy density ($B_T^2/8\pi$) in the magnetotail, where B_T denotes the magnetotail field in the high latitude lobe, and the substorm index $AE(nT) \approx \bar{U}_1/10^{15} \text{ erg s}^{-1}$ (ref. 10). Figure 1 shows the relationship between these three quantities monitored by the Explorer 34, 35 satellites and auroral zone magnetic observatories, respectively. This particular magnetotail event was chosen because it has been well documented¹¹. For the relative location of the satellites with respect to the magnetosphere, see the insert in Fig. 1.

Figure 1 shows that the three quantities, ϵ , $B_T^2/8\pi$ and AE vary roughly in harmony. Note particularly the occurrence of two substorms which are clearly indicated by an increase of the AE index; the corresponding auroral activity was well recorded in Alaska. If one assumes that the magnetospheric substorm is produced by an explosive conversion of the magnetic energy stored in the magnetotail before substorm onset, $B_T^2/8\pi$ should begin to decrease rapidly at $T=0$, namely at ~ 11.00 UT and ~ 15.30 UT, respectively. On the contrary, $B_T^2/8\pi$ increased with ϵ and the AE index at least during the main epoch (11.00–12.10 UT and 15.30–16.20 UT) of the expansive phase.

An important implication of this result is that the development of magnetospheric substorms is a direct consequence of increasing ϵ and the solar wind-magnetosphere dynamo power P . As the power is increased, both the magnetotail (solenoidal) current and the auroral electrojet are enhanced, as can be seen in the corresponding increase of $B_T^2/8\pi$ and AE . Note, however, that we assume here that the total volume of the magnetotail is not reduced appreciably. It has already been shown that ϵ and the AE index are related statistically by $AE(nT) \approx \epsilon/(10^{16} \text{ erg s}^{-1})$ for $\epsilon < 10^{19} \text{ erg s}^{-1}$ (ref. 10) although in this particular case, $AE(nT) \approx 2\epsilon/(10^{16} \text{ erg s}^{-1})$. Auroral activity manifests typical features of the substorm when the accompanying magnetic variations exceed about 100 nT (ref. 12); so that substorm activity is associated with $\epsilon \geq 10^{18} \text{ erg s}^{-1}$.

Note that although hourly values are used in computing ϵ , there seems to be an appreciable time delay between $\epsilon(t)$ and $AE(t)$. Such a delay can easily be expected for the magnetospheric circuit, as its inductance is known to be of the order of ~ 100 –500 H. Since the total ionospheric resistance is of the order of 0.1 Ω , the time constant of the system is of the order of ~ 17 –85 min. Thus, the magnetosphere cannot respond instantly and fully to changes of ϵ . Any storing of energy should occur during the period when the dynamo power is increasing, not before substorm onset.

On the basis of Fig. 1 and similar events, there is little doubt that the magnetospheric substorm develops when the solar wind-magnetosphere dynamo is being driven harder than during a quiet period. The magnetospheric substorm is not simply a process by which the total magnetic energy is stored before its onset and then is explosively consumed. Further, it begins to subside as ϵ decreases, not because stored energy is consumed. Therefore, this clarifies why the magnetic energy conversion subsides at the end of substorms (as a large amount of magnetic energy is still available then or even during a quiet time).

The magnetospheric substorm may be said to be a direct consequence of increasing power generated by the solar wind-magnetosphere dynamo above $\epsilon > 10^{18} \text{ erg s}^{-1}$. Part of the increased current is channelled to the ionosphere along magnetic field lines. There are at least two important consequences of the increased field-aligned currents. The first is that the field-aligned currents develop a particular potential structure (called the V-shaped potential)¹³. As a result, the current-carrying electrons are accelerated downward and produce the aurora as they collide with polar upper atmosphere particles. As auroral electrons are accelerated to a few kilovolts, the auroral arc will suddenly brighten. An increased ionisation and conductivity might have a positive nonlinear effect¹⁴. The second consequence of the increased field-aligned currents is the generation of the auroral electrojet; a large increase of the Joule heat production (responding to a large increase of the power generation) can take place.

It may perhaps be premature to generalise this finding to other phenomena which have been suspected to be caused by a sudden magnetic energy conversion. On the other hand, the magnetosphere is the only region in which the hypothesis of an explosive magnetic energy conversion can be tested¹⁵. In this respect, solar flares have also been believed to be due to such an energy conversion process. Indeed, there is a close phenomenological similarity between magnetospheric substorms and solar flares; in fact, flare ribbons may be identified as solar auroras¹⁶. Although details are given elsewhere¹⁶, note that for a vertical wind of speed $V = 1 \text{ km s}^{-1}$ across horizontal magnetic field lines of $B = 500 \text{ G}$ in an area S of $10^5 \text{ km} \times 10^5 \text{ km}$, the dynamo power is given by $P = (B^2/8\pi) \times S \times V \approx 10^{29} \text{ erg s}^{-1}$. Therefore, as in the case of auroral substorm, in spite of its sudden onset, a solar flare could be a direct result of a photospheric dynamo process. In fact, it has been shown that a solar flare tends to occur in the vicinity of a newly emerging magnetic flux¹⁷, so that this emerging flux is likely to be an indication of the presence of such a dynamo process.

The effect of compressible flow on anti-dynamo theorems

J. P. Todoeschuck & M. G. Rochester

Department of Physics, Memorial University of Newfoundland, St John's, Newfoundland, Canada A1B 3X7

The 'anti-dynamo' theorems (ADTs) impose restrictions on the symmetry properties of the velocity and magnetic fields associated with sustained dynamo action in an electrically conducting body of fluid, such as the Earth's core. However, several of these ADTs depend on the assumption that the fluid flow is incompressible, and we show here that their validity is queried when compressible flow is considered. In particular, non-stationary axisymmetric dynamos may no longer be prohibited by Cowling's theorem. The high degree of axisymmetry of Saturn's magnetic dipole, revealed by the recent Pioneer 11 flyby, may be related to the planet's large compressibility.

The first and best-known of the ADTs is Cowling's¹ (extended by Backus and Chandrasekhar²), which proves the impossibility of supporting a stationary axisymmetric magnetic field **B** by axisymmetric fluid motions. The essential point in Cowling's argument is that motional induction cannot maintain **B** in the vicinity of the 'neutral' curve **B** = 0, so the latter region is a sink of magnetic energy¹. If the requirement of stationarity is relaxed, this decay may be offset by diffusion into this region of field produced elsewhere in the conducting fluid body, and the proof of the ADT apparently fails. However, Cowling's theorem was later^{3,4} generalised, using a different proof based on global properties of the field, to forbid even non-stationary axisymmetric dynamos.

There seems to be a widespread impression that Lortz⁵ has shown that even the requirement of axisymmetry in the velocity field **v** can be abandoned without weakening Cowling's theorem, but Lortz's argument rests subtly on an assumption about axisymmetry of the electric field which in turn forces **v** to be axisymmetric.

Cowling's theorem has played an important part in the development of dynamo theory. It contributed to the scepticism with which several eminent physicists greeted Elsasser's pioneering studies in the 1940s and early 1950s. The widely felt suspicion that a more general and thoroughly prohibitive ADT might exist was not totally dispelled until 'existence proofs' were found independently by Herzenberg and by Backus in 1958. The necessity of avoiding the consequences of Cowling's theorem also decisively guided the Bullard-Gellman-Lilley-Gubbins and Braginskii approaches to a plausible terrestrial dynamo model.

Elsasser⁶ argued convincingly, and rigorous proofs were provided by Bullard and Gellman⁷ and by Backus⁸, that a toroidal **v** could not maintain dynamo action. This ADT has generally been interpreted as requiring **v** to have a non-zero radial component in a working dynamo. Analogous to this constraint is the impossibility of dynamo action when **v** lacks a component in one cartesian direction⁹. Cowling³ recognised that the toroidal **v**, two-dimensional, and non-stationary axisymmetric ADTs are but special cases of a single class of theorems whose proofs use global properties of **B** and **v**. Other ADTs have been conjectured¹⁰, but apparently the only other for which a rigorous proof exists is that prohibiting a stationary dynamo in a sphere when **v** is purely radial¹¹.

An almost universal assumption in dynamo theory is that the fluid flow can be treated as incompressible—that **v** is solenoidal, $\nabla \cdot \mathbf{v} = 0$. An exception to this is the paper by Namikawa and Matsushita¹¹, who remark that "a curl-free velocity field may be important for the dynamo maintenance of the magnetic field in the Earth's core". Also Krause and Roberts¹² find that, when

the electrical conductivity is low enough, finite compressibility can assist dynamo action in mirror-symmetric turbulence, but not enough to actually bring about regeneration.

As Smylie and Rochester¹³ have shown, the assumption of solenoidal flow is not permissible for large-scale radial motions in the stratified liquid core of the Earth. The relative importance of compression by transport through the pre-existing hydrostatic pressure field is measured by the dimensionless number $C = gL/c^2$, where g and c are representative values for gravity and compressional wave speed in the liquid core, and L is the radial length scale of the motion. Only for $C \ll 1$ can the flow be treated as solenoidal. For the Earth's core, $C \sim 0.1$ when $L \sim 10^6$ m. The neglect of compressibility may therefore be of questionable validity for dynamo mechanisms which do not depend on small-scale turbulence in the core.

Among the most interesting consequences of taking compressibility into account are those for the ADTs which rest on 'global' proofs. Cowling's original 'neutral-curve' argument¹ is not dependent on any assumption of solenoidal flow, so his theorem forbidding a strictly stationary axisymmetric dynamo is unaffected. The same is true of the radial-**v** ADT discovered by Namikawa and Matsushita¹¹. But the proofs^{3,4} of the three other ADTs, using global properties of the fields, fail when a lamellar part $\nabla \mathcal{L}$ is added to **v**. Separate clear standard proofs for each of these ADTs have been collected recently by Moffatt¹⁴.

The 'uncurled' hydromagnetic induction equation for axisymmetric **B** and **v** leads to the equation

$$\frac{d}{dt} \int_{V_\infty} \frac{\chi^2}{2\lambda} dV + \int_{V_\infty} (\nabla \chi)^2 dV = \int_{V_\infty} \frac{\chi^2}{2\lambda} \nabla^2 \mathcal{L} dV \quad (1)$$

where λ is the magnetic diffusivity, V_∞ is all space, and $\chi = -r \sin \theta (\partial P / \partial \theta)$ is the flux function associated with the poloidal part of **B**, $\mathbf{B} = \nabla \chi \times (\nabla \times \mathbf{r} P)$. Here r and θ are the usual spherical polar coordinates. If the RHS of equation (1) vanishes, we have Moffatt's equation (6.24), from which it is clear that the poloidal magnetic field must ultimately decay. But this conclusion is no longer assured for flows such that $\nabla^2 \mathcal{L}$ is non-negative in some finite region of space. A similar result is obtained for the toroidal part of **B** by the appropriate modification of Moffatt's equation (6.27). If U is a representative value of the radial component of the lamellar part of **v**, then $\nabla \cdot \mathbf{v} \sim UC/L$, and equation (1) indicates that the proof of this ADT is lost if $UC/L > 2\lambda/L^2$, that is if $CR_m > 2$, where $R_m = UL/\lambda$ is the magnetic Reynolds number. This requirement does not seem too difficult to meet in the Earth's core, and should be even easier to satisfy in an even more compressible planet such as Saturn. The possibility that non-stationary axisymmetric dynamos can be sustained by lamellar flow deserves investigation.

By definition a toroidal **v** is solenoidal and has no radial component. If the first of these conditions is relaxed as above, but with $\partial \mathcal{L} / \partial r = 0$, Moffatt's equation (6.41) is replaced by the equation

$$\frac{d}{dt} \int_V Q^2 dV + 2\lambda \int_V (\nabla Q)^2 dV = - \int_V Q^2 \nabla^2 \mathcal{L} dV \quad (2)$$

where $Q = \mathbf{r} \cdot \mathbf{B}$, and V is the volume of the conducting fluid (in which λ is supposed uniform). When its RHS vanishes, equation (2), together with Moffatt's equation (6.46) (which is similarly affected by lamellar flow), yields the ADT for toroidal **v**. But clearly the usual interpretation (that a radial component of **v** is required for dynamo action) may be voided if sufficiently compressible flow is allowed. However, because of the large non-radial compression required to violate it, the proof of this ADT for non-radial **v** remains valid in the Earth's core, at least. The prohibition against dynamos driven by plane two-dimensional motion⁹ may be similarly withdrawn in principle by permitting compressible flow.

We conclude that the usual proofs of several ADTs are nullified by abandoning the requirement of strictly solenoidal flow. We do not yet know if this means that the theorems themselves are invalid for compressible flow—that alternative

proofs independent of the incompressibility assumption cannot (or that counter examples can) be found. We do suggest that allowing for the physically real compressibility of electrically conducting fluids in planets may considerably relax (or remove) the constraint imposed by one of the ADTs, and permit the construction of non-stationary axisymmetric dynamos. For evidence that this result is not of purely academic interest we cite: (1) the likelihood, based on the known history of the Earth's magnetic field, that physical dynamos are essentially nonstationary on a wide range of time scales; (2) the recent discovery by Pioneer 11, that Saturn's magnetic dipole is highly axisymmetric¹⁵.

Anomalous high uranium contents in the sediment under Galapagos hydrothermal mounds

Claude Lalou & Evelyn Brichet

Centre des Faibles Radioactivités, CNRS-CEA, 91190 Gif sur Yvette, France

The geochemical behaviour of uranium and thorium in metalliferous sediments and hydrothermal deposits has been widely studied and the main results have been summarised by Boström and Rydell¹. These isotopes may be used to clarify how the metal-rich solutions are introduced into sediment cover and seawater. Using radiochemistry followed by α spectrometry, we have measured uranium concentrations as high as several hundred p.p.m., which must clearly be associated with ocean ridge thermal activity, in sediments interbedded between the basaltic basement and the green hydrothermal mud at DSDP Site 424. These high uranium concentrations indicate the path followed by the hydrothermal fluid which, debouching at the sediment–water interface, formed the green mud.

Very high uranium concentrations have been reported in East Pacific Rise (EPR) metalliferous sediments by Boström and Rydell¹ who found, on a carbonate-free basis, average value of 38 p.p.m. (maximum 62 p.p.m.). In the metalliferous sediments of Red Sea Brines, a maximum value of 31.3 p.p.m. has been found². The highest value presently reported for uranium concentration is 150 p.p.m. (CaCO₃-free basis) for a level in core GS-7202-35 (14°47' S, 113°30' W)³. However, in metalliferous sediments near the basaltic basement at DSDP sites 37, 38 and 39, only a weak enrichment in uranium was found⁴. The high concentrations are generally attributed to the scavenging of seawater uranium by the precipitation of iron hydroxides when hydrothermal solutions debouch in the seawater as the ²³⁴U/²³⁸U ratio in these deposits is close to the isotopic ratio of seawater. When higher isotopic ratios are found, they are considered to be due to hydrothermal leaching from basalt without subsequent important mixing with seawater uranium; the uranium content is generally relatively low⁵.

During DSDP Leg 54, four holes have been drilled at Site 424, an area of mounds previously described^{6–9} and of presumably hydrothermal origin. A relatively detailed description of the drill-holes (424, 424 A, B and C) drilled about 22 km south of the spreading axis (00°35' N, 86°07' W) is given by Hékinian *et al.*¹⁰ and Natland *et al.*¹¹. Some lithological data are available^{10,11}: the mean sedimentation rate in the area, calculated from Site 425 is 4.5 cm kyr⁻¹, if a constant and regular sedimentation rate is accepted for the 83-m thick sediment blanket covering a 1.8 Myr-old basement.

The schematic lithological sequence in holes 424, 424 A and B is, starting at the basaltic basement:

(1) a layer of pelagic sediment (referred to here as the basal sediment), essentially Foraminifera and nannocalcareous ooze, with thicknesses of 18.5, 13 and 13.5 m at each hole respectively,

(2) a relatively thick (15 m) layer of hydrothermal deposit formed with a green clay-rich material. This clay is essentially formed with nontronite,

(3) capping the whole: in holes 424 and 424 A drilled directly on the mounds a Mn oxide-rich layer is found, while in hole 424 B, between the mounds, the iron rich hydrothermal deposit is capped with calcareous sediments.

Fig. 1 a, ²³⁴U/²³⁸U activity ratio variations in the three drilled holes. Depths in the holes (m) have been arbitrarily calculated from the basaltic basement and are approximate values. Letters represent the laboratory number of the samples (see Table 1). O, values found in hole 424; V, values found in hole 424 A; X, values found in hole 424 B. Bars represent uncertainties calculated as one standard deviation (1 σ) derived from counting statistics. Solid line indicates present seawater ratio (1.14); dashed line indicates the ratio for a seawater uranium deposited 300,000 yr ago (1.060); dotted line indicates the ratio for seawater uranium deposited 600,000 yr ago (1.026). b, ²³⁴U/²³⁸U activity ratio versus uranium concentrations (symbols as in a).

* Activity ratio.

 \dagger Corrected for a 300,000 yr decrease of ^{234}U excess (see text).The uncertainties are one standard deviation (1σ) derived from the counting statistics.

Natland *et al.*¹¹, using the age of the basement (about 0.6 Myr), the thickness of the basal sediment (about 15 m) and a sedimentation rate of about 5 cm kyr^{-1} , arrive at an age of 300,000 yr for the hydrothermal event. This conclusion is corroborated by the finding of two acoustic reflectors⁷ which can be attributed to this anomalous layer, the lowest one pinching on the crust, about 12 km from the Galápagos rift, on a crust about 300,000 yr old¹¹.

From the previous preliminary studies^{10,11} the two hydrothermal formations, green mud and manganese oxides, must have been deposited by two different events, the first one 300,000 yr ago, during which reducing conditions prevailed, the second one, recent and perhaps always active, in oxidising conditions.

We consider here the detailed study of the uranium and thorium content, and of the $^{234}\text{U}/^{238}\text{U}$ activity ratio in the basal sediment, deposited between 600,000 and 300,000 yr ago. The study of the distribution of these nuclides and of possible disequilibrium in the series in the hydrothermal mud, the manganese deposit and the upper sediment layer will be described elsewhere¹².

Uranium and thorium in the basal sediment were measured by α spectrometry, using either a solid state detector or a ionisation chamber, associated with a multichannel pulse height analyser. Uranium and thorium were separated and purified by co-precipitation, solvent extraction, ion exchange and final extraction with 1-(2'-thenoyl)-3,3,3-trifluoroacetone, followed by evaporation of the solution on stainless steel plates. As a spike, we used a ^{228}Th solution in secular equilibrium with ^{232}U . No measurements were made without the spike to verify that the equilibrium between natural ^{228}Th and ^{232}Th was achieved, because we only had about 1 g of sediment for each level and as ^{232}Th concentrations are so low that even if a disequilibrium were to exist, this would not greatly affect the results.

These sediments being very rich in Foraminifera and nannocalcareous ooze, which are low in uranium (0.1–0.13 p.p.m.)¹³, then dilute the authigenic or detrital uranium, the uranium and thorium concentrations are given in Table 1 on a dry and carbonate-free basis. Table 1 also shows the CaCO_3 content, the $^{234}\text{U}/^{238}\text{U}$ activity ratios, and the $^{234}\text{U}/^{238}\text{U}$ activity ratios corrected for a possible decrease during 300,000 yr.

A striking enrichment in uranium is seen, amounting to 500 p.p.m. in hole 424 B, core 4, section 1, 95–96 cm, but also affecting the basal sediment of the two other holes. In contrast, the green hydrothermal mud has a very low uranium content (0.2–0.9 p.p.m.), as does the recent sediment in hole 424 B (0.9–5 p.p.m., CaCO_3 free)¹².

In contrast ^{232}Th is depleted relative to normal pelagic clays (13 p.p.m. (ref. 14)), which may indicate that the non-carbonate

fraction contains very few detrital clays. Nevertheless, ^{232}Th concentrations are higher than in the green hydrothermal mud (about 1 p.p.m. (ref. 12)).

The first important point is that, in contrast with other metaliferous deposits, the uranium enrichment is not found in the hydrothermal deposit, but in the sediment below. Two hypotheses may explain this high uranium concentration in the sediment.

First, the uranium was concentrated from seawater in a reducing environment before the hydrothermal event which gave the green mud. In fact, in normal oxygenated marine environment uranium stays in solution, but high authigenic concentrations are encountered in shallow anaerobic sediments; concentrations amounting to 40 p.p.m. have been found in the organic-rich sediments of the Norwegian fjords¹⁵. Concentrations of the same order of magnitude associated with high molybdenum concentrations have been measured in a sediment core by Turekian and Bertine¹⁶ who interpret them "as reflecting in part the formation of local ephemeral basins along the ridge, and in part the result of the high supply of organic material". Bonatti *et al.*¹⁷ in core P 6702-59 ($20^\circ 45' \text{N}$, $85^\circ 20' \text{W}$) have found an increase of uranium content with depth that they attributed to a change in redox potential and more recently, Mangini and Dominik¹⁸ have reported high values of uranium for eastern Mediterranean sapropels.

If this origin is retained for our samples, the seawater uranium was concentrated between 600,000 and 300,000 yr ago, period during which the basal sediment accumulated. If so, according to the $2.48 \cdot 10^5$ yr half life of ^{234}U , and with the assumption of closed system for uranium, the original $^{234}\text{U}/^{238}\text{U}$ activity ratio of seawater would have decreased from 1.14 (ref. 19) to 1.060 for uranium deposited 300,000 yr ago, and to 1.026 for the one deposited 600,000 yr ago.

Figure 1a shows the values of the measured ratios. Only three present a $^{234}\text{U}/^{238}\text{U}$ activity ratio compatible with the 600,000 yr value, and two with the 300,000 yr value. All the others are higher and five of them are even higher than the present seawater value.

However, this hypothesis would not explain why low $^{234}\text{U}/^{238}\text{U}$ ratios are associated with the highest uranium content (Fig. 1b). As Ku²⁰ has already shown, the postdepositional mobility of ^{234}U means that the hypothesis of closed system for uranium in sedimentary material is no more valuable. In fact, Mangini and Dominik¹⁸ have also found, in a 28-cm thick sapropel layer, the same inverse relation between $^{234}\text{U}/^{238}\text{U}$ ratio and uranium concentration, but, in this case, associated with a strong concentration gradient. They explain the variation of $^{234}\text{U}/^{238}\text{U}$ ratio by a half closed system, in which ^{234}U excess from seawater is in a closed system, while ^{234}U *in situ* produced

by radioactive decay is mobile. This mobile fraction is able to diffuse along the concentration slope, leading to an excess of ^{234}U in the low uranium material. As Kolodny and Kaplan²¹ have shown, in phosphorite the mobility of ^{234}U is due to the differential oxidation state of ^{234}U , $^{234}\text{U}/^{238}\text{U}$ being <1 in the U(IV) fraction and >1 in the U(VI) fraction.

In the case of Mediterranean sapropels, formed during anoxic periods, the uranium certainly originates in seawater. In hole 424 sediments, the presence of benthic Foraminifera (*Cassidulina laevigata*) indicates the presence of oxygenated waters at the sediment-water interface during deposition, so that the origin of uranium cannot be seawater.

Second, the concentration of uranium is of hydrothermal origin, its precipitation being due to the reducing conditions of the hydrothermal event. This is corroborated by the fact that the hydrothermal fluid was largely reducing as it has

given reduced iron deposits, even debouching in oxygenated seawater.

Hekinian *et al.*¹⁰ proposed two models for the mode of emplacement of these hydrothermal deposits. In the first model, there is a diffuse interaction with the sediment of an hydrothermal fluid from a deep-seated source. In the second model, the mounds are the narrow vents whose fluids do not interact with the sediment. From the uranium data, we conclude that the hydrothermal fluid has percolated through the sediment. Because of the steep gradient of uranium concentration, and the quantity of uranium mobilised in such a phenomenon, we suggest that the vents are not far from the mounds.

We thank Dr J. Labeyrie, J. C. Duplessy, R. Chesselet, L. Labeyrie and Dr K. K. Turekian for helpful comments. The NSF provided the samples. This study has been partly supported by DGRST grant 78-7-2197.

Possible late Quaternary pingo remnants in central London

J. N. Hutchinson

Department of Civil Engineering, Imperial College, London SW7 2BU, UK

Active pingos are ice-cored mounds formed within permafrost¹. Actual and suspected remnants of such features have been reported widely¹⁻⁷ from former periglacial and glacial areas of the British Isles (Fig. 1)⁸⁻¹⁰. They are characteristically located in slope-foot situations with associated present-day springs or poor drainage⁴⁻⁶. Most of the observed features lie between the latitudes of The Wash and River Thames and are generally thought to have originated as open-system pingos¹¹ in the late Devensian. No pre-Devensian pingos have hitherto been recognised. Here I suggest that many of the anomalous, drift-filled, closed depressions in the surface of the rockhead (usually the London Clay) beneath some of the central London terraces, recently reviewed by Berry¹², are the partly eroded remains of former open-system pingos, dating both from the Devensian and from earlier cold stages of the Pleistocene.

These drift-filled depressions have been revealed by engineering works in central London from the late nineteenth century onwards¹². In their upper parts they seem to be of smooth contour and shaped like a wide funnel, oval in plan. In plan, the widths across their minor axes lie between about 20 and 150 m: the ratio of these to the dimensions of the major axes range generally from ~0.4 to 0.9. Their lower parts are less regular, narrower and steeper-sided (Fig. 2), in one instance featuring a buried vertical cliff of London Clay more than 12 m high. At least five of the reported depressions completely penetrate the London Clay. In these cases, the underlying stratum (generally the Woolwich and Reading Beds) has risen diapiirically into the lower parts of the depression, typically by 6-12 m. In one of the several examples where the London Clay has apparently not been penetrated, a vertical tongue of this material at least 4 m high has diapirised upwards into the base of the drift-filled depression. The maximum confirmed depth of the depressions below the general trend of the bench surface is ~25 m.

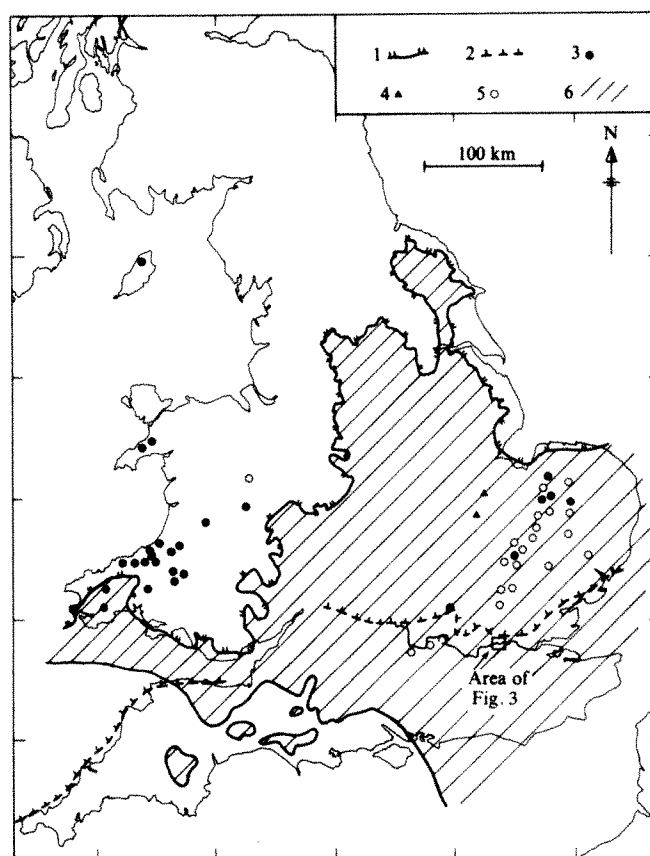

Fig. 1 Interim distribution of actual and possible pingo remnants in southern Britain, in relation to former maximum ice limits. (Acknowledgements to Committee for Aerial Photography, University of Cambridge, A. Taylor and J. Rose.) 1, Maximum southern extent of Devensian ice⁸; 2, maximum southern extent of pre-Devensian ice⁹; 3, localities of probable open-system pingo remnants in relief^{1-3,5,6}; 4, localities of possible closed-system pingos⁷; 5, localities where soil- or crop-marks indicate possible remnants of pingos or other ground ice features; 6, inferred distribution of extensive permafrost in the Devensian¹⁰.

It has been variously proposed that these features were formed by subsidence into solution cavities in the underlying Chalk¹³ (now generally discounted¹²), by some type of periglacial action^{12,14}, or by fluvial scour^{12,15}. The latter hypothesis has recently been reinforced by evidence for strong fluvial erosion during the late Devensian in stiff cohesive material in the channel of the River Gipping, Suffolk¹⁶. We accept that the anomalous depressions found in London have probably suffered major modification through fluvial scour, but do not consider that this mechanism can explain the origin of the features.

It is suggested here that many of these depressions originated as open-system pingos in the London Clay bedrock during the Devensian or earlier cold stages of the Pleistocene, deriving their water supply from artesian sub-permafrost or intra-permafrost groundwater through an unfrozen pipe or root. With the onset of interglacial or interstadial conditions, the collapsed pingo mounds would have been readily eroded away by the swollen rivers, to leave their roots exposed to local fluvial scour. This will have tended to enlarge and streamline at least the upper parts of the pingo roots, with corresponding replacement of some of the original infill by fluvial sediments. Some of the features may have been sheltered enough, or active sufficiently late, to suffer only minor modification.

The above hypothesis is supported by:

- (1) The general distribution of pingo remnants in Britain (Fig. 1), which indicates that conditions favouring the formation of open-system pingos may well have existed in the London area during the Devensian and will certainly have obtained there during earlier cold periods of the Pleistocene.
- (2) The inference, from the relation of the features to their infill, that the anomalous depressions in the London Clay were initiated in the "later stages of (late Quaternary) cold periods¹²", when the conditions of discontinuous permafrost usually associated with open-system pingos^{17,18} would have been likely to exist.
- (3) The observation that some of the depressions (such as, 3b)¹² have apparently been infilled partly by reworked London Clay^{12,19}, which may have been derived from the collapse and sloughing of a pingo mound.

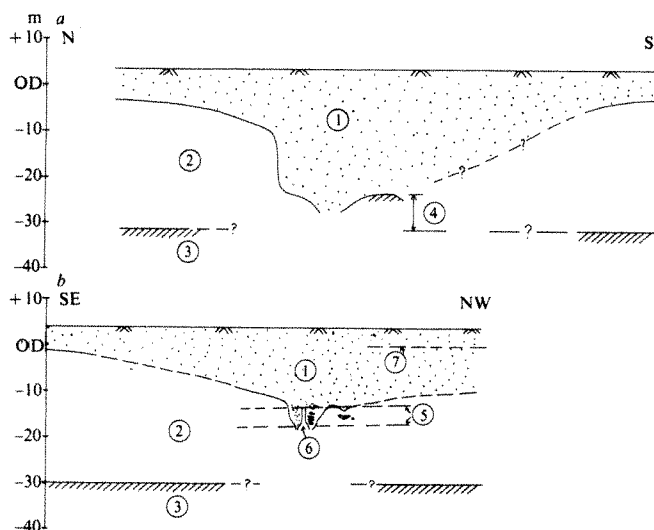

Fig. 2 Outline natural scale cross-sections of two of the anomalous depressions in central London, described by Berry¹²: a, N-S section of anomaly 1g, New Covent Garden, which penetrates the London Clay: 1, drift (chiefly sands and sandy gravels; sometimes clayey); 2, London Clay; 3, Woolwich and Reading Beds; 4, anomalous rise in level of junction of 2 and 3. b, NW-SE section of anomaly 2d, Vauxhall Grove, which appears not to penetrate the London Clay: 1-3, as for a; 5, Northbound tunnel of Victoria Line; 6, vertical tongue of London Clay; 7, general level of London Clay bench surface in the surrounding area.

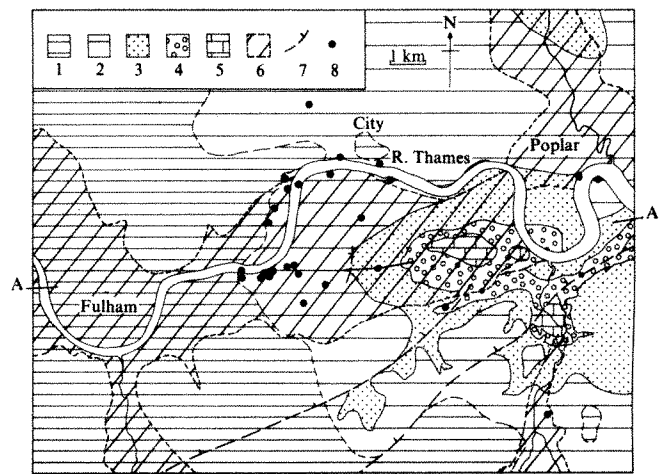

Fig. 3 Distribution of reported anomalous depressions in central London¹² in relation to the sub-crops of solid strata beneath the drift and to the estimated areas of former flowing artesian groundwater²⁰: 1, London Clay, greater than 35 m thick; 2, London Clay, less than 35 m thick; 3, Woolwich and Reading Beds; 4, Thanet Beds; 5, Upper Chalk; 6, former natural flowing artesian areas; 7, faults; 8, location of known anomalous depressions.

- (4) The distribution of the reported anomalous depressions in central London, which shows that: (i) Nearly all the depressions lie within, or close to, the former flowing artesian areas of this part of the London Basin²⁰ (Fig. 3). This suggests that groundwater conditions favouring open-system pingo formation^{11,21,22} are likely to have been present at the time when these features originated. (ii) The reported depressions occur mainly in the

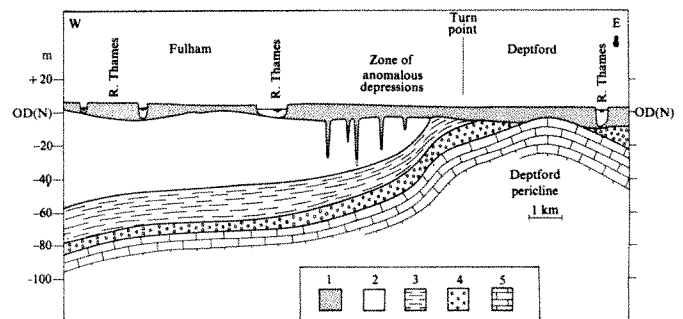

Fig. 4 Section A-A (Fig. 3) along the Thames Valley showing the relationship of the anomalous depressions to the feather-edge of the London Clay against the Deptford pericline: 1, Made ground and drift; 2, London Clay; 3, Woolwich and Reading Beds; 4, Thanet Beds; 5, Upper Chalk. Vertical exaggeration, $\times 50$.

feather edge of the London Clay stratum as it thins out against the inlier of Lower London Tertiaries and Chalk produced by the Deptford pericline (Fig. 4). In particular, they are restricted to the zone in which the present thickness of the London Clay is less than ~ 35 m (Figs 3 and 4). Bearing in mind that for open-system pingo formation a restricted supply of water is required^{11,21}, the absence of depressions from the artesian tracts where the London Clay is thicker may be the result of an inadequate upward groundwater flow. Conversely, their rarity in the artesian areas where the Lower London Tertiaries and the Chalk form the rock-head may indicate that in these localities the groundwater discharged too rapidly for pingo growth and

formed surface icings or naleds²² instead. (iii) The depressions show a propensity to cluster, generally in slope-foot or valley bottom situations; a characteristic that is entirely consistent with an open-system pingo origin^{1,17,18,21}. They are also sometimes located near stream junctions; a feature that has been taken to indicate a fluvial scour origin^{12,15}, but it is not unusual for open-system pingos to occupy such locations²³.

The deeper structures of active and fossil pingos have as yet been little explored. Nevertheless, with regard to the diapirism observed in the basal parts of the London depressions, it is noteworthy that the upward displacement of underlying strata into the base of pingo systems has been suggested in several instances²⁴⁻²⁶.

If the above proposals are valid, it will be possible to define more closely the areas of London where further anomalous depressions in the London Clay surface can be expected. Likewise, remnants of open-system pingos should be found in association with analogous artesian areas elsewhere in southern and central Britain.

Interaction between chemoreceptive modalities of odour and irritation

William S. Cain & Claire L. Murphy

John B. Pierce Foundation Laboratory and Department of Epidemiology and Public Health, Yale University, New Haven, Connecticut 06519

Inhaled vapours may stimulate both olfactory receptor cells and endings of the trigeminal nerve¹. The trigeminal nerve often contributes a pungent, irritating attribute to odours. Many odorants exhibit some pungency when dilute and most become pungent when concentrated². Because the trigeminal system commonly shares the chemosensory burden with olfaction, it is relevant to ask whether these anatomically distinct systems interact³⁻⁶. Two obscure psychophysical observations argue for an inhibitory influence of trigeminal over olfactory activity. Katz and Talbert observed that a vapour with both odour and pungency might lose odour at high concentrations, irritation masking odour⁷. The nineteenth century philosopher Alexander Bain, noting that concentrated carbon dioxide (carbonic acid) evokes pungency, remarked "if a current of carbonic acid accompanies an odour, the effect (odour) is arrested" (ref. 8). We have taken up Bain's forgotten observation and used carbon dioxide to endow otherwise benign concentrations of odorant with varying degrees of pungency. The experiments reported here reveal a strong mutual interaction between pungency and odour, occurring without attenuation even when irritant enters one nostril and odorant the other.

In the first experiment, eight persons judged the perceived magnitude of four concentrations of the fruity odorant *n*-amyl butyrate [0.7–12.2 parts per million (p.p.m.)], presented olfactometrically, four concentrations of carbon dioxide [10–50 parts per hundred (p.p.h.)], and all 16 combinations (mixtures) of the two. Subjects inhaled the stimuli through one nostril (flow rate: 4 l min⁻¹). They assigned numbers proportional to sensory magnitude⁹, judging a stimulus first for overall magnitude and then for either the odour component (half the trials) or the irritating component. Each subject made 240 judgments over five sessions.

In the second experiment, 10 subjects followed the same psychophysical procedure with dichorhnic 'mixtures' (4 l min⁻¹ flow rate into each nostril with equal numbers of right-left and left-right combinations of odorant and irritant). In such condi-

Fig. 1 a, Perceived magnitude (linear scale) plotted against concentration of carbon dioxide (logarithmic scale) for carbon dioxide presented alone (●), amyl butyrate presented alone (■) and mixtures of carbon dioxide and amyl butyrate (○). The concentration of amyl butyrate (p.p.m.) is indicated at the left in each case. Data points are medians taken across eight subjects. b, Same as a, but combinations of carbon dioxide and amyl butyrate were presented dichorhnically, that is irritant (carbon dioxide) to one nostril and odorant (amyl butyrate) to the other. Data points are medians taken across 10 subjects. c, Perceived odour component (denoted odour magnitude) of amyl butyrate alone (■), carbon dioxide (●) and physical mixtures (○). The low, but non-zero judgments for the 'odour' of the odourless irritant carbon dioxide presumably reflect imperfect perceptual resolution between odour and irritation. The non-monotonic function formed by the thin dashes depicts how odour magnitude would change in a case where concentration of odorant and irritant changed jointly. d, Same as c, but dichorhnic mixtures.

tions, the nasal septum insulated odorant from irritant but the sensory 'image' was essentially indistinguishable from that produced by a physical mixture¹⁰.

If the olfactory and trigeminal systems did not interact, the families of functions in Figs 1a, b and 2a, b would comprise

parallel lines. The converging trend reveals inhibitory interaction. Figures 1c, d and 2c, d depict the pattern of the inhibition for each perceptual component. Just as the perceived magnitude of carbon dioxide alone increased sharply with concentration (Fig. 1a, b), so did its ability to inhibit any accompanying odour (Fig. 1c, d). Similarly, just as the perceived magnitude of amyl butyrate alone grew gradually with concentration (Fig. 2a, b), so did its ability to inhibit irritation (Fig. 2c, d).

Figures 1 and 2 reveal a fundamental similarity between the physical (monorhynchic) and dichorhynchic mixtures. Because it rules out interference between odorant and irritant at the mucosal surface, dichorhynchic inhibition seems to establish the generality of the olfactory-trigeminal interaction beyond the stimuli used here. It also suggests that the interaction occurs in the brain.

The explanation of dichorhynchic inhibition must not ignore possible bilateral peripheral phenomena, such as changes in nasal patency¹. Such changes could arise from reflex vasodilation, which could increase intranasal resistance and diminish accessibility of the olfactory mucosa¹. To account for inhibition of odour, however, this mechanism would require the trigeminal response to precede the olfactory response consistently, an unlikely outcome in view of previous results^{11,12}. The trigeminal system generally seems to react to chemical stimulation slowly. The third experiment supported this view in a comparison of reaction times to carbon dioxide alone and amyl butyrate alone (Fig. 3a). Six subjects each made 400 responses over five sessions. Both odour and irritation exhibited intensity-dependent latencies, but at any given level of perceived magnitude the reaction to amyl butyrate always preceded that to carbon dioxide. The reaction to carbon dioxide was too slow to support the possibility that it generally inhibited odour magnitude through reflex changes in nasal patency.

The fourth experiment gave temporal advantage to the irritant to investigate whether peripheral factors are involved in the interaction between odour and pungency. Thirteen subjects (each making 96 judgements over three sessions) assessed the magnitude of amyl butyrate after inhalation of either 30 p.p.h. carbon dioxide or pure air. Each subject sampled the adapting stimulus (carbon dioxide or air) for 2 s followed immediately, on

Fig. 3 *a*, Simple reaction time to four concentrations of amyl butyrate and to four concentrations of carbon dioxide plotted against the perceived magnitude of the stimuli. Data points are means (± 1 s.e.m.) taken across six subjects. *b*, Perceived magnitude of amyl butyrate smelt for 2 s immediately after 2-s inhalations of pure air (half the trials in each session, generally every other trial) or 30 p.p.h. carbon dioxide (other half of the trials). Data points are means (± 1 s.e.m.) taken across 13 subjects.

Fig. 2 *a*, Same psychophysical data as Fig. 1a, but plotted here against concentration of amyl butyrate. Symbols as follows: ●, amyl butyrate alone; ■, carbon dioxide alone; ○, physical mixtures. The concentrations of carbon dioxide (p.p.h.) are indicated at left for each. *b*, Same as *a*, but dichorhynchic mixtures. *c*, Perceived irritating component of carbon dioxide alone (■), amyl butyrate alone (●) and physical mixtures (○). *d*, Same as *c*, but dichorhynchic mixtures.

the same inhalation and through the same nostril, by amyl butyrate (2 s). In these conditions, carbon dioxide reduced odour intensity by about 12% (Fig. 3b). Simultaneous presentation had reduced odour intensity more than four times this amount (Fig. 2c, d). Accordingly, even in favourable temporal conditions, peripheral factors seem relatively impotent.

Because, if potent enough, an olfactory stimulus generally serves also as a trigeminal stimulus, olfactory-trigeminal interaction must be frequent. So far, the inhibitory interaction has revealed itself unambiguously only in the extreme case, such as where the inherent pungency of an 'odorant' outstrips odour magnitude, causing it to fall with increases in concentration^{7,12}. Figure 1c, d depicts how odour would first increase and then decrease with joint (co-varying) increases in the concentration of carbon dioxide and amyl butyrate. These non-monotonic functions could reflect how the odour of a single stimulus with both odour and pungency varies with concentration¹². Hints that such functions might emerge from central olfactory structures appear in observations that benign odorants will stimulate so-called background activity in the olfactory bulb, whereas 'sharp, unpleasant odors' will inhibit such activity^{13,14}. Walsh even noted a specific inhibitory effect of carbon dioxide on single units of the olfactory bulb (cats)¹⁵. These units also responded to the somaesthetic (trigeminal) stimulation caused by inhalation of odourless air.

Thus, we have confirmed, quantified and extended a century-old observation that pungency can diminish odour. We show: (1) a continuum of inhibition, (2) mutuality, whereby odour inhibits irritation and vice versa, (3) apparent generality beyond particular olfactory or trigeminal stimuli, and (4) a central neural site of interaction. The dimensions of the interaction may depend on various factors. Irritants will undoubtedly vary in their affinity for olfactory receptors. Even carbon dioxide, although odourless, might conceivably cause some unspecified modulation of olfactory receptors. Manner of trigeminal activation may also have a role; perhaps trigeminally mediated warmth, cold or pressure can modulate odour. Finally, the timing of olfactory and trigeminal activation may be involved. Differences in speed

of activation from odorant to odorant and irritant to irritant, not necessarily revealed best by simple reaction time, may govern any contribution from peripheral factors. Irrespective of the mechanism of the interaction, our results suggest a need for special attention to odorous and irritating contaminants in the workplace. An irritating gas may mask the presence of useful olfactory signals (such as, warning agents) and an odorant may mask the possibly corrosive vapours (for example, inorganic acids) that often form the stimulus for the trigeminal nerve.

Illusory reversal of extrafoveally perceived displacement

D. M. MacKay

Department of Communication and Neuroscience, University of Keele, Keele, Staffordshire ST5 5BG, UK

It has long been known that the temporal characteristics of human peripheral vision differ markedly from those of foveal vision. Slowly moving peripheral stimuli, for example, can give rise to dramatically exaggerated estimates of their displacement^{1,2}. More recently, Thorson *et al.*^{3,4} have shown that where two spots are flashed in sequence to peripheral vision with an interflash interval of 50 ms, a sensation of movement can be induced even when the spatial separation of the spots is below the static acuity threshold. These observations fit with several others^{5,6}, suggesting that the visual system uses separate channels for signalling 'motion' as distinct from 'change of location', and that in some circumstances the integration of motion signals may make a dominant contribution to the perception of displacement. I now report a striking illusion which seems to reinforce and extend this conclusion.

This illusion is easily demonstrated and quantified using a double-beam cathode-ray oscilloscope with a non-persistent screen in a normally lit room. If one spot (or line) on the screen is deflected instantaneously through 1° or 2° and allowed to return more slowly to its original position, for example by alternate (1 s⁻¹) exponential-spike waveforms of 25 ms time constant and opposite polarity (Fig. 1a), then in foveal vision its motion is perceived more or less veridically. Viewed 3° or 4° extrafoveally, however, the appearance is surprisingly different. The displacement perceived is actually in the opposite direction to the real, the apparent motion being as shown in Fig. 1b. The illusion is readily quantified⁷ by imposing an RC-filtered step deflection of this form on the second cathode-ray tube beam, and adjusting its amplitude and time constant until the motion of the second

spot or line, when viewed foveally, seems to match that of the first (perceived extrafoveally). Detailed measurements are still in progress and will be reported elsewhere, but for photopic stimuli viewed at retinal eccentricities of a few degrees, the motion perceived is just as if the rapid displacements had not occurred. Furthermore, if fixation is changed so that both stimuli are viewed extrafoveally, their perceived motions still seem to match.

It thus seems that in these conditions only the slow phases of the image motion are signalled by the extrafoveal system to the centres that mediate motion perception. As the resting position of the spot (between spikes) remains physically unchanged (Fig. 1a), but is perceived as displaced alternately by an amount $\pm x$ (Fig. 1b), extrafoveally perceived location seems here to be computed entirely by integration from motion signals, rather as in an 'inertial navigation' system. (The rising phase of the spike, which takes only a few microseconds, is presumably too rapid to stimulate any physiological 'motion detectors' (ref. 8).)

Fig. 1 a, Waveform of deflection of extrafoveally viewed spot (spike deflections $\sim 1^\circ$, 1 s⁻¹). b, Waveform of perceptually matching deflection of foveally viewed spot. For perceptual match, $y = x$ and time constants are equal.

Note that the displacement x (Fig. 1a) was here much larger than the static acuity threshold for the extrafoveal region stimulated. When a square wave of the same amplitude was substituted for a, the spot motion was clearly perceptible. The present illusion is thus distinct from, and in a sense complementary to, the Thorson effect^{3,4} described above.

Further experiments have shown that at scotopic light levels (with only the retinal rods active) the perceptual match between the foveal and extrafoveal stimuli of Fig. 1 breaks down. This suggests that the computation of extrafoveal displacement on the basis of motion signals is primarily a function of the cone system. In this connection it may be significant that it is normally only at scotopic light levels (when the cone system is inactive) that illusory instability of the perceived world is seen during saccadic eye movements. The findings reported here suggest that at photopic levels the processing of extrafoveal information may be undisturbed by the image displacements produced by normal saccadic exploratory movements.

Young kittens can learn complex visual pattern discriminations

Frances Wilkinson

Department of Psychology, University of Western Ontario, London, Ontario, Canada N6A 5C2

Peter C. Dodwell

Department of Psychology, Queen's University, Kingston, Ontario, Canada K7M 3N6

Kittens begin to display visually elicited responses shortly after eye opening. The pupillary reflex¹, optokinetic response^{2,3}, visual placing³⁻⁵ and avoidance of the deep side of the visual cliff^{3,5-7} all appear between the second and fifth weeks of life, and evidence of visual learning in homing behaviour has been described at the same early age⁸. However, an attempt to elicit pattern preferences in kittens of this age (usually considered the easiest way to demonstrate discriminatory behaviour in immature organisms⁹) was unsuccessful, evidently because such kittens show little spontaneous visual interest^{10,11}. This is surprising in view of electrophysiological findings which emphasise the importance of the fourth to sixth weeks in the development of cortical feature-analysing mechanisms¹²⁻¹⁴, perhaps the stimulus-seeking methodology of Dodwell *et al.*^{10,11} is inappropriate for the visual modality at such an early age. Recently, visual acuity measurements have been reported for kittens as young as 30 d of age using a contour versus no-contour discrimination on a modified Lashley jumping stand^{15,16}. With this technique we have now trained kittens of under 50 d of age to perform more complex pattern discriminations.

In the jumping stand, kittens have to jump from the lip of a short tunnel on to one of two stimulus surfaces, a drop of 15–20 cm. The surfaces are trapdoors, and an incorrect choice results in a fall of about 45 cm. Correct choices are rewarded with food and petting. An average kitten is able to perform this task adequately at 28–30 d of age, thus setting a lower age limit to its use. To accustom the animals to the jumping stand and to obtain an initial estimate of their learning ability, all kittens are pretrained on a white/black discrimination (white positive). The 20 kittens in our experiment all exhibited either an immediate preference for white, or learning within 80 trials. Accustoming the animal to jumping, black/white training, and gradually increasing the jumping height to a maximum of 15–20 cm, takes 5–10 d, thus placing the onset of pattern discrimination training between the 35th and 40th day of life.

Different groups of kittens of this age were trained to discriminate each of the three pattern pairs shown in Fig. 1. These stimuli constitute the three basic orthogonal orbit-pairs of Hoffman's Lie transformation group theory of pattern perception (ref. 17 and P.C.D., unpublished) and were chosen for that reason; the theory predicts that they will be the easiest patterns to discriminate, particularly for an immature animal¹⁷. However, patterns similar to pairs *a* and *b* have been widely used in the study of visual perception (refs 18–20 and P.C.D., unpublished) pair *b* in particular having been generally regarded as the simplest possible pattern discrimination because its resolution involves only orientation detection²⁰. Pair *c* (families of rectangular hyperbolae) have not been used before. The stimuli were photographic enlargements of these patterns mounted on 32-cm² white cards and plasticised. The black contours were 1.5 cm wide, thus subtending visual angles of slightly more than 4° of arc when viewed from a height of 20 cm. This should be well within the visible range for kittens at 35 d of age¹⁵. Each stimulus pair was matched as closely as possible for overall luminous flux.

Kittens were given 40 training trials per day until the criterion of 27 of 30 consecutive trials correct was met. The number of trials (excluding the final 30) and errors to criterion for the three groups are shown in Table 1, with the age at which criterion was reached. Clearly, kittens are able to master each of these problems very early in life. For comparison, we have included data for problem *a* from seven older kittens (mean age at criterion 80 d), some of which had previously learned other problems and some of which were experimentally naive. Both young and older kittens showed similar performance, so apparently the young group made use of visual pattern information in a normal manner throughout the training period, and learning was not impaired by visual or motor immaturity. This is probably true also of problems *b* and *c*, but we do not yet have sufficient data to confirm the point. The results in Table 1 suggest that for very young kittens the problems increase in difficulty from *a* to *c*. We are now investigating whether or not this is an age-dependent phenomenon.

Solution of each discrimination problem was followed by a series of transfer tests. These were designed to rule out the involvement of various extraneous cues and to determine to which aspects of the stimulus configuration the animals were responding. Transfer tests were typically administered by a different investigator from the one who administered the training trials; in no case did performance deteriorate as a result of this change. On the basis of the perfect or near-perfect transfer scores obtained, such factors as olfactory cues, auditory and visual cues associated with locking the trapdoors, and visual cues specific to the particular pair of stimulus cards used in training could be ruled out. A full description of the methodology and results of these tests will be published elsewhere.

Fig. 1 The three pattern pairs derived from Hoffman's Lie transformation group theory.

Table 1 Summary of learning scores

Problem	No. of kittens	Trials to criterion	Errors to criterion	Age at onset of training (d)	Age at criterion (d)
a	9	115 (40–218)	53 (19–99)	38 (35–40)	43 (38–47)
b	4	271 (97–435)	113 (49–225)	38 (35–40)	48 (38–58)
c	4	327 (163–562)	138 (79–239)	38 (33–43)	48 (46–51)
a (late)	7	119 (42–187)	53 (21–89)	76 (45–120)	80 (48–123)

Results given are the mean; the range is given in parentheses. Group *a* (late) consisted of the four kittens from problem *b* group, one kitten from problem *c* group, and two experimentally naive kittens.

For problems *a* and *c* the most crucial test was the contrast-reversal test, in which the stimuli were negative photographic enlargements of the same original patterns. The contrast relationships within each figure were thus reversed, as was the direction of any overall luminance difference between figures. This test was given to 14 of the 16 animals trained on problem *a* and three of the four kittens trained on problem *c*. Contrast-reversal test trials were intermixed with training trials on the original stimulus pair. Food reward followed all test trials regardless of the animal's response whereas, on training trials, the reinforcement contingencies described above were used. The range of transfer scores fell between 7/10 and 10/10 correct, with a mean of 9.0. This constitutes fairly strong evidence that the kittens were not solving the problems on the basis of overall luminous flux or local brightness cues, thus suggesting that they coded the features of the patterns as a whole, and independently of contrast.

We have thus demonstrated that kittens between 30 and 50 d of age can be taught arbitrary associations between certain visual patterns and positive and negative rewards. This seems almost paradoxical in view of the earlier finding that kittens show little, if any, spontaneous interest in visual stimulation at this age¹⁰. The apparent anomaly can probably be accounted for in terms of the extrinsic rewards associated with our present training procedure. Nevertheless, the findings reported here open the way for investigating the ontogeny of visual pattern analysis under much tighter experimental control than is provided by the naturalistic situations in which visual learning has previously been described in very young kittens⁸. Our initial results indicate that at the peak of the so-called 'critical period', when neurones of the visual cortex are most sensitive to environmental modification^{21,22}, kittens are able to extract and use visual pattern information in a rather sophisticated manner, albeit from patterns which, from a certain theoretical point of view, are the simplest ones available.

A demonstration of navigation by small rodents using an orientation cage

Janice G. Mather & R. Robin Baker

Department of Zoology, University of Manchester, Manchester M13 9PL, UK

The ability to 'home' after displacement has been demonstrated for several species of small mammals¹. Whether such homing is accomplished by random scatter², familiarity with a large area^{3,4} or some kind of navigation mechanism⁵ is still unknown. The ability to navigate (to determine the direction that will lead the animal to the required destination⁷) has been shown, for example, by releasing displaced rodents on snow and analysing their tracks⁶ and by analysing for homeward bias the directions from the release point of traps in which displaced individuals were subsequently recaptured¹. Such techniques are limited in application. Moreover, the latter technique is susceptible to differential avoidance of traps by animals travelling in different directions³. It is potentially more useful to retain displaced individuals in an orientation cage and to examine their movements within the cage for evidence of orientation in the homeward direction. However, previous attempts using various types of orientation cages have yielded only negative results^{8–10}, except, surprisingly, when the displaced animals could not see their natural surroundings. We present the first positive evidence that small rodents will navigate while retained in an orientation cage, even when able to see their surroundings. Indeed, we show that these visual cues are important in navigation and suggest why orientation cages have previously led to negative results.

Our main experimental species was the European wood-mouse, *Apodemus sylvaticus* although the yellow-necked mouse, *A. flavicollis*, and bank vole, *Clethrionomys glareolus*, were occasionally tested when available. In all, 19 individuals were used (*A. sylvaticus*, ten males and four females; *A. flavicollis*, one male; *C. glareolus*, two males and two females) in a total of 116 4-minute test periods on 72 displacement occasions. Although mainly nocturnal, *Apodemus* spp. are known also to be active during the day, particularly juveniles (unpublished observations and refs. 11 and 12). It was presumed, therefore, that if they had navigational ability, these species, like the more diurnal *C. glareolus*, ought to be able to make use of cues available during the day as well as the night. It was also anticipated, and borne out by this work, that a nocturnal animal would show a strong homing response during daylight.

All experiments were conducted between 10.00 and 17.30 h GMT between 11 and 25 July 1979 at Woodchester Park Field Centre, Gloucestershire. Animals were caught in Longworth traps, either in a meadow (12 traps in a 110-m line) or in woodland (96 traps in a 70 m × 110 m grid described by Yalden¹³). The woodland was situated above the meadow on the same north-west facing slope of an enclosed V-profiled valley. The orientation cage designed for this work and the experimental procedure are described in Fig. 1 legend. After testing, the animal was either returned to the point of capture or released from the final displacement site and the vanishing point direction (the direction of last observed position from the test site) recorded. Vanishing point direction (up to 30 m from the test site) was often very different from the initial direction of movement after release, which, as found by other authors⁷, was usually aimed at the nearest cover.

Fig. 1 The orientation cage was a cross-shaped Perspex chamber with a black opaque floor and transparent sides and top. A mesh door at the end of each arm of the cross could be raised to allow the animal to exit. An activity wheel was positioned in each arm as part of a separate experiment but which incidentally (and importantly) provided shelter. After capture, each individual was identified and weighed, then placed in the apparatus through a circular hole in the centre of the lid. An opaque black polythene sheet was used to cover the apparatus during transport to each of the displacement sites where an area of level ground was selected. The apparatus was then positioned so that the four arms were directed towards magnetic north, south, east and west. The polythene sheet was then removed and the observers withdrew to a vantage point ~5 m away. The experimental animal was allowed to visit three of the four arms before recording began. Total time spent in each of the four arms was then recorded, but periods of grooming, which were often long, were excluded. The danger of subjectivity thus introduced was reduced by the fact that two observers were always present, each with a stopwatch. In practice, the beginning and end of grooming periods were clear-cut and exclusion was considered preferable to lumping the behaviour with periods of movement and environmental monitoring. Recording ceased after 4 min (excluding grooming time). Whenever possible, this experiment was repeated with the same individual at four displacement locations, each varying in distance and compass direction from the central point of capture. At each displacement site, the direction and distance of the trap, observers and nearest vegetation/cover were recorded and also weather conditions and time of day. The influence of smell of previous occupant was controlled by: (1) maintaining the same arm of the apparatus in a constant compass direction during each day's experiments; (2) varying the compass sector from 'home' (see Fig. 2) of the first test location for successive individuals; and (3) testing each individual at locations in more than one compass sector from home. Once navigation in the equipment had been demonstrated, possible visual and olfactory mechanisms were examined. At each displacement site various experiments were conducted involving the use of a visual barrier (a cardboard screen, 60 cm high and 35 cm radius, with a small hole 1 cm in diameter for observation) which surrounded the apparatus, and a partial olfactory barrier (perspex doors which were slotted in alongside the mesh doors).

Statistical analysis was carried out in two stages as described by Batschelet^{14,15}. Time spent in each of the four arms of the orientation cage was used in a first-order analysis to calculate the mean vector (r, θ) for each 4-minute test (Fig. 1). The mean angles were then subjected to second-order analysis¹⁵. Non-uniformity was examined by Rayleigh's Z -test¹⁴. Stephens' exact test and Wheeler and Watson's parametric two-sample test¹⁴ were also used, as indicated in Table 1 and Figs 2, 3.

In displacement experiments, the interpretation of navigational ability is very much dependent on the experimenters making the correct guess concerning the animal's intended destination. We had to presume that the animals were residents and that the point of capture was located centrally within the individual's home range, to which it would want to return after

being displaced. Hence, point of capture was taken to be the location of home towards which the animal would orientate while retained within the apparatus, and statistics are presented with trap direction designated as 0° . However, this is a particularly stringent criterion as the directions of the trap and intended destination are unlikely to be identical. Nevertheless, our results (Table 1) show that on average the mean orientation in the apparatus and the direction of movement after release are not significantly different and that vanishing point direction is not significantly different from the direction of the trap. We conclude that the mean orientation in our cage reflects the direction in which the animal would travel (after seeking cover) if unrestrained and that this direction is towards home.

The data were analysed with respect to a number of potentially confounding variables and the results are summarised in Table 1. The number of occasions an individual was caught in a Longworth trap does not influence performance. In contrast, the number of previous uses in the test apparatus does. Individuals used for the first and second times show a preferred orientation near to 'home' direction. However, for some reason as yet unknown, individuals being used on their third occasion showed uniform orientation.

The preferred orientation was not influenced by the position of the observer or the nearest vegetation cover, but was affected by weather conditions. At wind speeds less than force 3 (Beaufort Scale) orientation is most marked when the Sun is visible but is non-uniform even when not. However, winds of Force 3 or greater disrupt orientation with respect to home,

Fig. 2 Effect of displacement direction on mean orientation was shown by lumping data for displacements in four compass sectors around point of capture (trap position). All displacements 6–80 m from the trap are presented (excluding tests: (1) in wind speed of Force 3 or greater; (2) involving individuals being used on their third or more occasion; and (3) with a visual barrier). Each point (●, *Apodemus sylvaticus*; ■, *A. flavicollis*; ▲, *Clethrionomys glareolus*) represents the mean angle (θ , first-order analysis) for an individual during a 4-minute test period. Mean angle is expressed as positive or negative (+ or -) deviation from direction of trap of capture. All second order mean vectors (arrows) are significantly non-uniform. Mean vectors from N, E and S are not significantly different from trap direction (Stephens' exact test). From the W sector, the mean vector, although towards the trap, is significantly different from the trap direction. However, the inclusion of short-distance displacements (6–20 m) imposes a positive bias to the mean vector (see Fig. 3), an effect that possibly may have been compounded by some unslope orientation from this sector. We conclude that our animals were showing navigation in the orientation cage in the conditions and at the distances tested.

Table 1 Effect of various factors on orientation performance in the test apparatus: summary of second-order analyses

Variable	No. of tests (n)	Mean angle (θ°)	Mean vector (r)	Z	X	F	Exclusions*
<i>Home = 0°</i>							
Comparison of vanishing point direction (VP) with mean direction (MO) in test apparatus

Fig. 3 The accuracy of orientation was influenced by displacement distance. Displacements in all directions from the trap are shown, excluding tests influenced by wind and previous usage as described in Fig. 2. Diagrammatic conventions are as in Fig. 2 except that open symbols denote females and closed symbols males. All second-order mean vectors (arrows) for distances less than 80 m are significantly non-uniform. At short distances (<20 m), mean vectors are significantly different from trap direction (Stephens' exact test), probably reflecting the difference between the directions of the trap and intended destination, although the meaning of the clear positive deviation is unknown. At greater distances a positive bias is still evident, though not significantly different from trap direction. Beyond 80 m, orientation is not significantly non-uniform, but sample size is small.

whether the Sun is visible or not. Instead, at these wind speeds the animals orientated at right angles to upwind, thereby spending more time in the most sheltered arm of the apparatus.

Final demonstration of the occurrence of navigation towards home in the apparatus was achieved by examining mean orientation from four different compass sectors relative to trap position (Fig. 2). Navigation has been demonstrated for distances up to 80 m from point of capture (Fig. 3) which is nearly three times the distance of half the home range length (0.5×56.6 m) of male *A. sylvaticus* at Woodchester in summer¹⁶. However, 80 m is far less than the distance from which homing has been demonstrated for *Apodemus* spp. elsewhere (59% return from 250 m,

17% return from 750 m etc.)¹. This could imply that navigation is not used at these longer distances and that homing is achieved by other mechanisms such as random search (see Bovey¹ for discussion). However, our experimental animals were limited to cues available at the particular displacement site and had to reach a decision concerning home direction within a few minutes. Further experiments at longer distances are planned with the animals being allowed more opportunity to acquire and process information as to their location.

Other factors were examined (Table 1) but were found to have no significant effect on the direction of orientation. These factors included whether the displacement site was in open meadow or

woodland and time of day (the latter is not shown in Table 1). Nor were any overall differences found between males and females (see also refs 4 and 17). However, when displacement distance was considered, there was an indication that orientation was most accurate for females at distances less than 40 m but for males at distances between 40 and 60 m (Fig. 3).

An opaque screen surrounding the apparatus disrupted orientation (Table 1), supporting the suggestion that woodmice use visual cues for navigation^{18,19}. The addition of Perspex doors (in the absence of a screen) (Fig. 1) did not disrupt orientation (Table 1). However, all 11 individuals thus tested showed a decreased bias (that is, first-order r value) towards the mean angle compared with the bias when the Perspex doors were removed. This was due to an increase in the amount of movement in the apparatus when the doors were in position, all arms being visited more frequently and evenly. During this movement, the animals often climbed the bars to sniff at any gaps still remaining. Vision thus seemed to be the major sense involved in navigation but additional information may have been sought from olfaction.

Our experiments have shown that in certain conditions small rodents will orientate toward home while in an orientation cage and will do so at distances up to at least three times the radius of their home range. Visual and perhaps olfactory senses both seem to be involved. We suggest that our experiments produced

positive results because, unlike previous orientation cages, ours offered the animal shelter from the wind and the opportunity to take cover (under the running wheels) should it feel threatened. As a result, the animals orientated toward home rather than toward the nearest cover, the main cause of negative results in previous experiments.

Oestrogens regulate divergent effects of prolactin in the ovary

Johannes D. Veldhuis & James M. Hammond

Department of Medicine, Division of Endocrinology, The Milton S. Hershey Medical Center, The Pennsylvania State University, Hershey, Pennsylvania 17033

Prolactin exerts well established stimulatory effects both *in vitro* and *in vivo* in the rat ovary¹. However, in the ovary of higher mammals, prolactin action is not well characterised, and may differ from that observed in rodents². For example, in human clinical conditions of physiological or pathological prolactin excess, ovarian function is depressed³, and in isolated, human granulosa cells *in vitro*, prolactin seems to inhibit progesterone production⁴. To examine direct prolactin effects in the higher mammalian ovary, we have used an *in vitro* porcine granulosa-cell model⁵. In this system, prolactin action is bipotential, depending critically on the degree of granulosa-cell differentiation attained *in vivo*. Prolactin suppresses steroid production by cultured granulosa cells isolated from small (1–2 mm), immature follicles, but stimulates progesterone secretion by granulosa cells collected from large (>6 mm) mature follicles⁶. The present studies show that oestrogens may play an important part in regulating these divergent actions of prolactin in the ovary.

To investigate potential modulation of prolactin action by oestrogens, we maintained granulosa cells collected from immature porcine follicles in monolayer culture for 10–12 d. As previously observed, prolactin alone produces inhibitory effects (Fig. 1a). However, the continuous administration of oestrogens to granulosa cells produces a biphasic response and a striking oestrogen–prolactin interaction that is time dependent. Early in culture (days 0–2) oestradiol alone exerts dose-dependent inhibition of progesterone production. Oestradiol decreases the total mass of progesterone contained in cells and medium (data not shown), indicating a reduction in actual steroid synthesis rather than in steroid secretion alone. The range of inhibitory concentrations of oestrogens used *in vitro* encompassed that observed in porcine follicular fluid comprising the *in vivo* micro-milieu of immature to increasingly mature granulosa cells⁶. When prolactin is added to submaximally inhibiting concen-

trations of oestrogen during this initial culture period, progesterone secretion declines further. Thus, both oestrogen and prolactin exert inhibitory effects early in culture and these effects are additive at submaximal steroid concentrations.

After 48 h of continued oestrogen exposure, cultured granulosa cells exhibit a reversal in responsiveness to oestrogen effects, and show enhanced progesterone secretion. From day 2 onward in culture, oestradiol stimulates steroidogenesis, and, more strikingly, produces a 'switch' in prolactin action from inhibitory to stimulatory (Fig. 1b). The interaction of oestradiol and prolactin is synergistic in enhancing progesterone production on all days throughout culture after day 2 ($F > 20$, $P < 0.01$ by 2-way analysis of variance). The oestrogen effects exhibit steroid specificity. The stimulatory actions of oestrone ($1 \mu\text{g ml}^{-1}$) and 17β -oestradiol ($1 \mu\text{g ml}^{-1}$) were quantitatively similar, at 7.4 ± 0.7 and 8.7 ± 0.6 ng progesterone per 10^6 cells per 48 h, respectively, with control cultures 2.8 ± 0.3 (mean \pm s.e.m., $n = 4$, $P < 0.01$ by one-way analysis of variance). However, the less potent oestrogen, oestriol ($1 \mu\text{g ml}^{-1}$), exerted no significant effect (2.1 ± 0.25), and the anti-oestrogen, nafoxidine hydrochloride (10^{-7} M), produced slight but insignificant suppression of steroid secretion (1.6 ± 0.2). Although oestrogens are mitogenic for granulosa cells *in vivo* and *in vitro*⁷, oestrogenic effects cannot be accounted for by simple alteration in cell number. 17β -oestradiol ($1 \mu\text{g ml}^{-1}$) increased the number of cells per culture by only $28 \pm 9\%$ above control ($n = 18$ experiments). Thus, when progesterone accumulation is corrected for cell density, both the acute inhibitory and the delayed stimulatory changes in progesterone secretion persist at various times in culture (Fig. 2).

In addition to modifying granulosa-cell responsiveness to prolactin, oestrogens seem to exert important intrinsic effects on steroid secretion by the ovary. *In vivo* and *in vitro*, oestrogens in conjunction with gonadotropins facilitate follicular maturation and steroidogenesis in several species^{7–9}. However, inhibitory effects of oestrogen on granulosa cell progesterone secretion have also been described^{10–14}. The present study demonstrates that the action of oestrogen may be bipotential, and critically dependent on the duration of hormone exposure. Acute oestrogen administration produces inhibitory effects, concordant with observations by Haney *et al.* in porcine granulosa cells¹⁰, and with work by other investigators in luteal tissue of the cow¹¹, ewe¹², monkey¹⁴ and human¹⁴. However, our findings also reveal delayed, but sustained stimulatory effects of oestrogen. A similar response to chronic oestrogen exposure in

replicating cultures has been reported by Bernard *et al.* in rat¹⁵ and by Goldenberg *et al.* in pig granulosa cells *in vitro*¹⁶, but was not observed by Thanki and Channing when cultured porcine granulosa cells were maintained in serum-restricted conditions of stationary growth¹⁷. These observations suggest that factors related to cell proliferation must also be considered in the expression of oestrogen action in the ovary.

The directional reversal of prolactin action induced by oestrogens *in vitro* is similar to that which occurs spontaneously during maturation of porcine ovarian follicles *in vivo*^{5,18}. Granulosa cells of the pig may differ in this regard from those of the human (in the latter, prolactin seems to suppress progesterone secretion regardless of follicle size)⁴. This difference may reflect species characteristics, or exemplify the requirement to select mature, 'pre-ovulatory' follicles. Such follicles are exposed to high endogenous oestrogen concentrations *in vivo*, and are required in our system to demonstrate stimulatory effects of prolactin *in vitro*. Because intrafollicular oestrogen

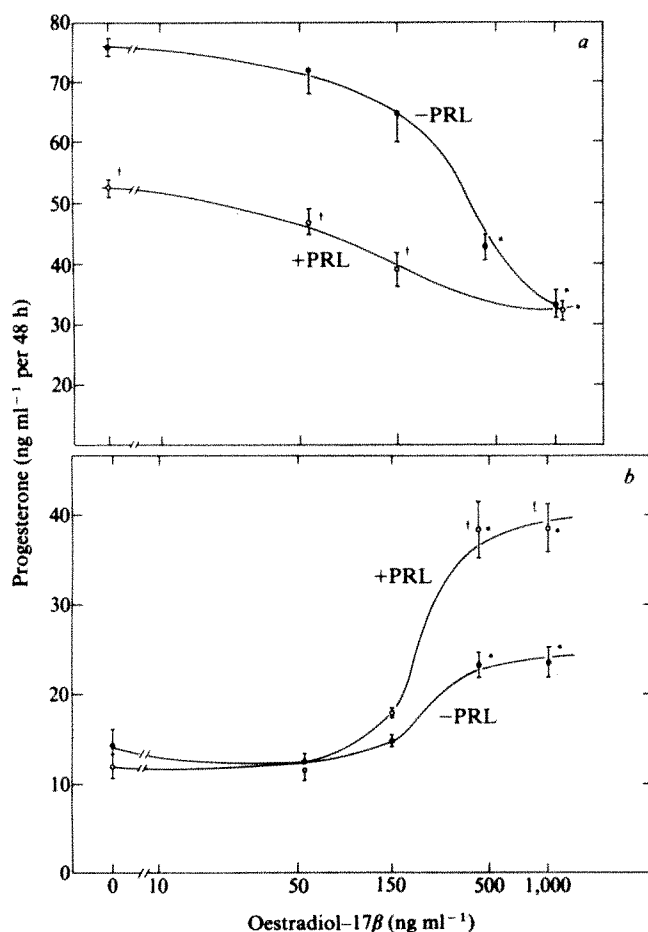

Fig. 1 *a*, Day 2, Acute oestrogen administration to cultured porcine granulosa cells suppressed progesterone production in a dose-dependent manner. Prolactin (PRL) (100 ng ml⁻¹) further inhibited progesterone accumulation in the presence of sub-maximal oestradiol concentrations. *b*, Day 4, Continuous oestrogen exposure enhanced progesterone secretion and reversed the inhibitory action of prolactin. The interaction of oestrogen and prolactin was synergistic in augmenting steroid accumulation ($F > 20$, $P < 0.01$ by 2-way analysis of variance). Granulosa cells were aspirated from 1–2-mm follicles of porcine ovaries and maintained for 2–10 d in monolayer culture (medium 199, 10% fetal calf serum, bicarbonate buffer and antibiotics⁵). Quadruplicate cultures were treated with increasing concentrations of 17 β -oestradiol, in the presence or absence of prolactin (100 ng ml⁻¹, NIH-oPRL-S12). Spent medium was removed at 48-h intervals for the subsequent determination of progesterone by radioimmunoassay²³. Data are mean \pm s.e.m. ($n = 4$). * $P < 0.01$ compared with basal (no oestrogen, no prolactin); † $P < 0.01$ compared with oestrogen treatment without prolactin.

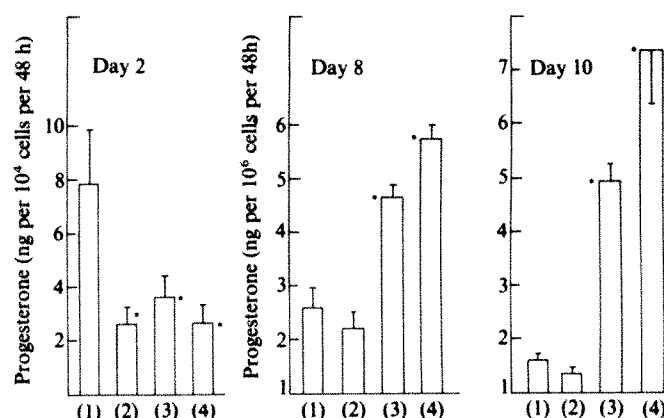

Fig. 2 Acute inhibitory and delayed stimulatory interactions of oestrogen and prolactin on steroidogenesis in cultured porcine granulosa cells. Data are expressed as the mass of progesterone (ng) produced per 10⁴ cells (day 2), or per 10⁶ cells (days 8 and 10). Cultures were treated with ovine prolactin (100 ng ml⁻¹) (column (2)) or 17 β -oestradiol (1 μ g ml⁻¹) (column (3)) or both (column (4)), for 2, 8 or 10 days before enumeration of cell density by electronic (Coulter) particle counting⁵. Column (1) shows control levels. * $P < 0.01$ versus control.

concentrations increase 20–100-fold during follicular maturation *in vivo*^{19,20}, our observations of oestrogenic effects in cultured porcine granulosa cells suggest that oestrogens may govern the physiological responses of these cells to prolactin *in vivo* as well as *in vitro*.

The mechanism of the potent interaction between oestrogens and prolactin is a challenge of these studies. We previously demonstrated that porcine granulosa cells freshly collected from small immature follicles exhibit high concentrations of specific, high-affinity prolactin binding sites¹⁸, which are maintained during continuous monolayer culture⁵. Oestradiol seems to double prolactin binding by these cultured porcine granulosa cells²¹. However, a simple increase in prolactin receptor concentrations would fail to explain the directional reversal of prolactin effects in oestrogen-treated cells. Conversely, prolactin modification of cellular oestrogen binding must also be considered. For example, in rat luteal tissue *in vivo*, prolactin induces oestradiol receptors²², and is synergistic with oestrogen in enhancing steroidogenesis. However, regulatory changes at other cellular loci of hormone action will also require further examination, as the intracellular mechanisms subserving the actions of prolactin and the steroidogenic effects of oestrogens are poorly understood. Further investigation of the hormonally responsive ovarian cells used in the present studies should allow a more comprehensive understanding of the cellular basis for these critical hormone interactions in the mammalian ovary.

We thank the Hormone Distribution Office, NIAMDD, NIH, for ovine prolactin, the Shamokin Packing Corporation for porcine ovaries, Marlene Thompson for manuscript assistance, and Patricia Klase for technical support in the radioimmunoassays. Axons from CNS neurones regenerate into PNS grafts

P. M. Richardson, U. M. McGuinness & A. J. Aguayo

The Neurosciences Unit, Montreal General Hospital and McGill University, 1650 Cedar Avenue, Montreal, Canada H3G 1A4

Axons in the peripheral nervous system (PNS) and central nervous system (CNS) form sprouts after injury^{1–3}. Elongation of regenerating axonal sprouts has been observed as the exception within the adult mammalian CNS but is the rule in the PNS of mammals as well as in the CNS of some fish and amphibians⁴. The relative importance of intrinsic neuronal properties and axonal environment in determining the extent of axonal regrowth is unknown⁵. Neuroglial cells, nerve growth factor and target tissues such as smooth muscle are known to influence neuronal responses to injury^{6,7}. Here we have examined the capacity of transected axons originating in the CNS to regrow into nerve grafts containing Schwann cells.

The surgical technique used, a modification of that previously described^{8,9}, was carried out in young adult Sprague–Dawley rats. In the first group of 16 animals, a 5-mm segment of the midthoracic spinal cord was removed and an autologous sciatic nerve graft was inserted sub-pially between the two stumps of the spinal cord. One to four months later, the animals were anaesthetised and perfused. The grafts and adjacent spinal cord tissue were examined by light and electron microscopy. The perineurium surrounding the common peroneal and posterior tibial fascicles of the sciatic nerve was clearly identifiable in cross-sections through the middle of the graft and contained many myelinated or unmyelinated axons ensheathed by Schwann cells. The ultrastructural appearance of each graft was similar to that of a regenerated peripheral nerve. The grafts were in gross continuity with the proximal and distal spinal cord stumps. At the spinal cord–graft interfaces, small cysts were frequently found but were rarely greater than 1 mm in diameter. In electron micrographs, the marginal spinal cord tissue was seen to contain many astrocytic processes and to be surrounded by a basal lamina. Small, irregular dome-like neuroglial structures were observed to protrude towards the graft at the ragged edge of the spinal cord tissue. These protuberances resemble structures seen at the interface of optic nerve grafts and peripheral nerves¹⁰ and also at the normal dorsal root entry zone¹¹. Occasional fibres were found where the axon was surrounded by peripheral myelin (periodicity 15.0 nm) and Schwann cell cytoplasm on one side of a node of Ranvier and central myelin (periodicity 13.6 nm) and astrocytic processes on the other. From these morphological observations we conclude that some axons crossed the border between the graft and spinal cord, although the direction in which they grew could not be determined.

Because of the potential ability of axons in the dorsal and ventral spinal roots to innervate such grafts, all roots crossing the pia-arachnoid at the graft site as well as the corresponding dorsal root ganglia were avulsed in other rats. Grafts in rats with

avulsed dorsal root ganglia contained a mean of 5,850 myelinated axons (s.e. = 510, $n = 6$); those in rats with intact spinal roots and ganglia contained a mean of 10,950 myelinated axons (s.e. = 1,660, $n = 5$). These results suggest that dorsal and ventral roots contributed to the innervation of the grafts but were not the sole source of axons. They do not exclude the possibility that the grafts were entirely innervated by axons originating from dorsal root ganglia and motor neurones¹².

A third group of experiments were carried out to identify the cellular origin of axons in the graft. In 15 rats, a segment of the spinal cord at least 10 mm long was removed and a sciatic nerve graft of equal length was inserted. The roots were left intact. Three to four months later the operative site was re-exposed and horseradish peroxidase (HRP) was injected into the spinal cord immediately rostral or caudal to the graft. After 2 more days, each animal was killed and labelled neurones were sought in a 10-mm segment of the non-injected spinal cord stump, immediately adjacent to the graft (Fig. 1). After injection rostral to the graft, the mean number of labelled neurones seen in the caudal spinal cord stump was 48 (0, 8, 28, 40, 169); after injection caudal to the graft, the mean number in the rostral stump was 6 (0, 0, 1, 6, 23). In five control animals, the graft was crushed with jeweller's forceps immediately before HRP injection and no HRP was seen 2 d later in spinal neurones on the other side of the graft. We conclude that neurones in the experimental groups were not labelled spuriously because of interstitial diffusion through the graft, flow in the cerebrospinal fluid or extravasation into the systemic vasculature. Labelling is thought to have resulted from incorporation of HRP into axon terminals at or near the spinal cord–graft junction and retrograde axonal transport across the graft to perikarya in the adjacent spinal cord. In segments below the graft, labelled

Fig. 1 Left, 2–4 months after the original operation, HRP (20% Sigma VI) was injected through a glass pipette into the spinal cord immediately rostral (or caudal) to the sciatic nerve graft. The injection of small quantities of HRP (0.5 μ l in 30 min) was designed to minimise the possibility of a false positive result due to the extravasation of enzyme and not to label every axon crossing the graft. Vaseline was spread extradurally and subdurally about the graft before injection, dry cotton batting was placed about the pipette during the injection and mineral oil was injected through the pipette as it was withdrawn. Two days later, the animal was perfused with glutaraldehyde. From a 10-mm segment of the spinal cord immediately across the graft from the injection site, specimens were removed and rinsed overnight in sucrose buffer. Approximately 300 sections, each 20 μ m thick, were cut on a freezing microtome, mounted, incubated with tetramethyl benzidine and hydrogen peroxide and counterstained with neutral red²⁴. Right, composite diagram illustrating the position of labelled nerve cell bodies in the spinal grey matter below the graft in four animals after HRP injection above the graft. Each animal is represented by a different symbol. Few neurones are labelled in the tips of the dorsal horns and in the lateral portion of the anterior horns. Because of the small amount of HRP injected and the short length of the spinal cord surveyed, it is assumed that more spinal neurones project into the graft than are shown here.

Fig. 2 Histogram showing the diameters as measured under the light microscope, of perikarya in the grey matter of the lower thoracic cord (excluding the dorsal part of the dorsal horn and lateral part of the ventral horn). White columns represent neurones in a normal rat; dotted columns represent unlabelled neurones below the graft; black columns represent labelled neurones below the graft. Labelled neurones have a larger mean diameter than either control group.

neurones were scattered through the central part of the grey matter (laminae 4, 5, 7, 8, 10)¹³ (Fig. 1). Both small and large nerve cells were labelled and the diameter of HRP-containing neurones was slightly greater than that of unlabelled neurones in the same regions of the spinal grey matter (Fig. 2). Some anterior horn cells above the graft and some dorsal root ganglia at the level of the graft and several segments below or above it also contained labelled cells but the ganglia were not surveyed systematically. The evidence demonstrates that some axons originating from neurones within the spinal cord grew a distance of approximately 10 mm into a PNS graft. We do not know whether such axons then re-entered the spinal cord and formed synapses. No functional improvement attributable to axonal regeneration was observed in any animal.

Mammalian central neurones with recognised capacity for axonal regrowth over a distance can be placed in two groups. In the first group, which includes somatic motor neurones and autonomic preganglionic neurones, the axons project outside the CNS. Intrinsic CNS neurones with regenerative ability have been found in the hypothalamus¹⁴ and brain stem^{15,16}. The latter neurones are cholinergic or monoaminergic and are thought to have thinly myelinated or unmyelinated axons¹⁷. The findings reported here indicate that there are other neurones in the rat spinal cord also capable of axonal elongation after injury. Some of the HRP-labelled perikarya probably represent autonomic preganglionic neurones about the central canal¹⁸ or in the intermediolateral columns, but most of them were found in areas of spinal grey matter normally occupied by neither autonomic nor somatic motor neurones. None is likely to have been monoaminergic because cell bodies containing catecholamines or serotonin have not been discovered in the spinal grey matter¹⁹. In short, the labelled cells do not belong to a class of neurones in which axonal regrowth has been described previously. It is unknown whether or not spinal axons with regenerative potentiality have any specific anatomical or biochemical property.

Spinal axons such as those which grew into a peripheral nerve graft in these experiments have repeatedly demonstrated only abortive sprouting after simple transection^{1,20}. This evidence that the regenerative response of similar axons differs in CNS and PNS neuroglia, together with other experimental observations^{10,21,22}, supports the hypothesis that Schwann cells are more conducive to axonal regeneration than central neuroglial cells²³. The regenerative potentiality of CNS neurones may be expressed only when their neuroglial environment is changed.

Response to stress of mesocortico-frontal dopaminergic neurones in rats after long-term isolation

G. Blanc, D. Hervé, H. Simon*, A. Lisoprawski, J. Glowinski & J. P. Tassin

Groupe NB, INSERM U.114, Collège de France, 11, place Marcelin Berthelot, 75231 Paris Cedex 05, France

Recent studies suggest that the mesocortico-frontal dopaminergic neurones which originate in the ventral tegmental area (VTA) have an inhibitory role in locomotor activity^{1,2}. They are also markedly activated under stress³⁻⁵. This effect was shown in rats and mice subjected to electric foot-shocks by measuring either the rate of decline of dopamine (DA) after α -methylparatyrosine treatment³ or the changes in dihydroxyphenylacetic acid (dopac) levels and the dopac/DA ratio^{4,6}. In rats, stress-induced activation of the dopaminergic neurones was prevented by benzodiazepines^{4,5}, and studies in BALB/c mice introduced for 2 min into an open field further established the role of dopaminergic neurones in emotional responses⁷. These observations led us to examine the effects of long-term isolation on the activity of the mesocortico-frontal dopaminergic neurones in rats, some of which were subjected to a stressful situation. Indeed, several groups have reported that long-term isolation in rodents induced behavioural disturbances such as increased motor activity^{8,9} and aggression^{9,10} and hyper-reactivity to a new environment or stressful stimuli^{10,11}. As measured by the changes in dopac levels or the dopac/DA ratio, we report here that the activity of the mesocortico-frontal dopaminergic neurones was reduced after isolation. This was not the case for the dopaminergic neurones projecting to the nucleus accumbens or the striatum, the rate of DA utilisation in these structures was even enhanced in isolated rats in which the activity of the mesocortico-frontal dopaminergic neurones was markedly reduced. Finally, we will show that a 3-min electric foot-shock session is more effective in enhancing dopac levels or the dopac/DA ratio in the frontal cortex of isolated than grouped rats.

*Laboratoire de Neurobiologie du Comportement, Université de Bordeaux II, Rue Le's Saignat, 33076 Bordeaux Cedex, France.

Fig. 1 Effect of stress on the rate of dopamine (DA) utilisation in the frontal cortex of grouped or isolated rats. Rats were isolated or kept in groups for 8 or 12 weeks and then individually exposed to a 3-min electric foot-shock stress. Other isolated or grouped rats were used as respective controls. In all cases, DA (a) and dopac (b) levels were estimated in the frontal cortex and the dopac/DA ratio (c) was calculated for each sample. Results are the mean of data from two independent experiments in which similar changes were observed. They are thus the mean \pm s.e.m. of data obtained with 20 samples (10 animals in each case) and are expressed in per cent of respective control values. The mean values of DA, dopac and dopac/DA ratios in grouped and isolated rats, respectively, are 1,150, 325, 0.29 and 1,250, 300, 0.26. DA and dopac levels being expressed in pg per mg of protein. \square , Controls; \blacksquare , 3-min stress. * $P < 0.05$; ** $P < 0.02$; *** $P < 0.001$ when compared with respective control values.

Male Charles River rats (180–200 g) were kept in a controlled environment (24 °C, 60% humidity, alternate cycles of 12 h light (0700–1900 h) and darkness) and received food and water *ad libitum*. Some of them were isolated in opaque cages (28 \times 18.5 \times 12 cm) for at least 8 weeks, others remained grouped (46 \times 26 \times 20 cm), (five animals per cage). The isolated rats could hear and smell their congeners, but were unable to see, touch or otherwise interact with them. Isolated and grouped rats were killed the same day between 1100 and 1200 h. Their brains were immediately frozen and cut in 500- μ m coronal slices from which tissue samples were punched out in both frontal cortices (11,300 and 10,800 μ m slices)⁴. In some experiments, samples were also taken bilaterally from the nucleus accumbens (9,800 and 9,300 μ m) and the medial part of the striatum⁴ (8,800 μ m) which is mainly innervated by nigral dopaminergic cells. After separation on alumina microcolumns, DA and dopac levels were estimated with a radioenzymatic method and the dopac/DA ratio was determined for each sample^{4,12}.

From the results of five independent experiments carried out during a 10-month period, the mean dopac/DA ratio was found to have decreased in frontal cortices of isolated rats (0.24 ± 0.010 , $n = 50$ samples, -30% , $P < 0.001$) when compared with that of grouped animals (0.34 ± 0.014 , $n = 50$). This effect, which was mainly due to a decrease in dopac levels (-19% , $P < 0.01$), suggests that isolation reduced the activity of the mesocortico-frontal dopaminergic neurones. However, the decreased dopac/DA ratio observed in isolated rats varied between experiments (-4% , -19% , -32% , -35% , -43%), the effect being significant in three cases. This seemed to be related to variations in the mean values of the dopac/DA ratio in the grouped rats (0.27–0.41); the ratio was remarkably constant from one experiment to another in isolated animals (0.23–0.26). Seasonal rhythms¹³ and/or seasonal changes in emotional states could be responsible for the variations observed in grouped rats. Prolonged isolation may attenuate these fluctuations.

In two of the five experiments, half of the rats isolated for 8 weeks were grouped for 4 additional weeks. In this case, their cortical dopac/DA ratio was significantly higher than that estimated in rats isolated for 12 weeks, but not different from that of rats continuously kept in groups (Table 1). Therefore, the reduced activity of the mesocortico-frontal DA neurones induced by isolation is a reversible process.

In two experiments we examined simultaneously the reactivity of the mesocortico-frontal DA neurones in grouped and isolated rats exposed for 3 min in individual cages to electric foot-shocks⁴. Confirming previous results, this stress reduced the levels of DA and increased the dopac/DA ratio in the frontal cortices of grouped rats⁴. The effect was more pronounced in isolated animals, the increase in the dopac/DA ratio being twice that observed in grouped rats and mainly due to an increase in dopac level ($+73\%$) (Fig. 1). Because the absolute levels of dopac and the dopac/DA ratio were higher in isolated (519 ± 45 pg per mg protein, 0.50 ± 0.04 , $P < 0.05$) than in grouped (383 ± 36 pg per mg protein, 0.40 ± 0.03) rats, the enhanced reactivity of the DA neurones seen under stress in isolated animals cannot be attributed solely to their initial lower state of activity. The biochemical changes observed in isolated rats, which were identical to those previously seen in grouped animals exposed to a longer stress session (20 min)⁴ suggest that the intense activation of the DA neurones enhanced not only the rate of DA utilisation but also its synthesis. Behavioural differences were also observed: the grouped rats jumped during electric shocks and attempted to escape, whereas the isolated rats exhibited stereotypic and freezing behaviours during and between shocks, respectively. The grouped rats were highly reactive at the end of the 3-min stress whereas the isolated animals seemed exhausted.

Finally, in three of the five experiments we also compared the rate of DA utilisation in the nucleus accumbens and the striatum of isolated and grouped rats. The mean results show a slight but not significant enhanced utilisation of DA in these structures in isolated rats. This finding is in contrast with the effect observed in the frontal cortex. Moreover, in one experiment in which a pronounced reduction of the dopac/DA ratio was seen (-43%), significant opposite effects were obtained in the nucleus accumbens ($+36\%$) and striatum ($+33\%$) (Fig. 2).

Changes in monoamine metabolism in the whole brain of isolated rats or mice have already been reported. Despite some discrepancies, most authors found that the turnover rate of serotonin, noradrenaline and DA were reduced in isolated rats^{8–11}. In one study, DA turnover was decreased in the amygdala but was slightly increased in the olfactory tubercles and remained unchanged in the striatum and the nucleus accumbens¹⁴.

Our results extend previous findings and demonstrate that long-term deprivation of social interaction in rats reduced and

Fig. 2 Effects of isolation on the dopac/DA ratio in the frontal cortex, nucleus accumbens and striatum. Rats were isolated or kept in groups for 8 or 12 weeks and the dopac/DA ratio was estimated bilaterally in areas of the frontal cortex (a), nucleus accumbens (b) and striatum (c). For each structure, the results are the mean \pm s.e.m. of 30 samples (15 rats) and 10 samples (5 rats), respectively. They are expressed in per cent of corresponding values: 0.33, 0.15, 0.09 (30 samples) and 0.41, 0.18, 0.12 (10 samples) for the frontal cortex, nucleus accumbens and striatum, respectively. \square , Grouped; \blacksquare , isolated, mean of three independent experiments; \blacksquare , isolated, values of one of three experiments in which the maximal decrease in the cortical dopac/DA ratio was observed.

* $P < 0.02$, ** $P < 0.001$ when compared with respective control values.

Table 1 Reversibility of the effects of long-term isolation on the dopac/DA ratio and dopac levels in the rat frontal cortex

	dopac/DA	dopac (pg per mg protein)
Grouped (12 weeks)	0.40 ± 0.024	430 ± 35
Isolated (12 weeks)	0.24 ± 0.010	309 ± 19
	(-40%)*	(-28%)†
Isolated (8 weeks) then grouped (4 weeks)	0.31 ± 0.017	401 ± 24
	(+29%)‡	(+30%)‡

Rats were isolated or kept in groups (five per cage) for 12 weeks. Other animals were first isolated for 8 weeks and then grouped for 4 weeks. DA and dopac levels were estimated bilaterally in the frontal cortex and the dopac/DA ratio was calculated for each sample. Results are the mean of data obtained in two independent experiments in which similar changes were observed. Thus, values of the dopac/DA levels are the mean ± s.e.m. of data obtained with 20 samples (10 animals) in each case.

* $P < 0.001$; † $P < 0.01$ when compared with values obtained with grouped animals (Student's *t*-test). ‡ $P < 0.01$ when compared with values obtained with rats isolated for 12 weeks.

maintained at a low level the activity of their mesocortico-frontal dopaminergic neurones. Indeed, the cortical dopac/DA ratio was constant during a 10-month period and was lower than that observed in grouped animals. Furthermore, isolation enhanced the reactivity of the mesocortico-frontal dopaminergic neurones to stress, as a 3-min session of electric foot-shocks was more effective in enhancing the cortical dopac levels and dopac/DA ratio in isolated than in grouped animals. This suggests that under stress the transmission of messages responsible for the activation of the mesocortico-frontal dopaminergic neurones is facilitated by previous isolation.

In recent studies, we showed that mesocortico-frontal dopaminergic neurone activity was controlled by interneuronal regulations which differed from those of other VTA dopaminergic cells^{15,16}. The present results confirm these findings because, in contrast to that observed for the mesocortico-frontal dopaminergic neurones, the activity of the dopaminergic neurones innervating the nucleus accumbens was not reduced in isolated rats. In fact, the opposite occurred in both the nucleus accumbens and the striatum, when the cortical dopac/DA ratio was reduced to a large extent in isolated rats. These results agree with Carter and Pycock's recent observations suggesting that the mesocortico-frontal dopaminergic neurones exert an inhibitory role on the activity of dopaminergic neurones innervating subcortical structures². Indeed, these authors have shown that the specific destruction of fronto-cortical dopaminergic terminals in the rat not only enhanced the turnover of DA in the nucleus accumbens and striatum but also increased the locomotor activity and stereotypic effect of amphetamine².

We already know that the mesocortico-frontal dopaminergic neurones are involved in the control of locomotor activity^{1,2}, emotional behaviour^{4,17} and cognitive processes^{18,19}. Therefore, the prolonged reduced activity of the mesocortico-frontal dopaminergic neurones in isolated rats as well as their higher reactivity under stress could be responsible for the enhanced locomotor activity and hyperactivity seen in these animals.

We thank Mr G. Godeheu for his help in taking care of the animals. This study was supported by grants from INSERM (CL 79.5.362.6), DRET (79.077) and Rhône-Poulenc SA.

Cycloheximide-sensitive synthesis of substance P by isolated dorsal root ganglia

A. Harmar*, J. G. Schofield & P. Keen

Departments of Pharmacology and Biochemistry, Medical School, University Walk, Bristol BS8 1TD, UK

Substance P (Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH₂) may be used as a neurotransmitter by certain primary afferent neurones^{1,2}, particularly those carrying pain impulses³⁻⁷. Substance P-like immunoreactivity has been localised to the cell bodies of one population of dorsal root ganglion neurones by immunocytochemistry⁸. It is contained in vesicles^{9,10} in the central terminals of these neurones⁸, and has also been demonstrated in the peripheral terminals^{11,12}. As axons and terminals have very little capacity for peptide biosynthesis¹³, it is possible that substance P is synthesised and packaged in the perikaryon and transported to the terminals by an axoplasmic transport process. Consistent with this is the finding that substance P accumulates proximal to a ligature placed on the dorsal root¹⁴. There has, however, been no direct demonstration of the biosynthesis of substance P in the nervous system. We report here that rat dorsal root ganglia incorporate ³⁵S-methionine into substance P, characterised as authentic by immunoprecipitation followed by HPLC. There is a delay of 1-2 h between addition of label and its incorporation into substance P. Synthesis is blocked by cycloheximide suggesting that, in dorsal root ganglia, substance P is synthesised by a conventional ribosomal process. Synthesis of substance P is reduced by some 90% in ganglia from rats treated neonatally with capsaicin, a drug which is thought to destroy a population of primary afferent neurones¹⁵.

The anti-substance P serum was raised in rabbits using synthetic substance P (UCB Bioproducts) conjugated to succinylated thyroglobulin by the carbodiimide method. As expected with this coupling reagent, which reacts with the amino groups on residues 1 and 3 of substance P, the antiserum was directed to the C-terminal region of the peptide. The affinity of a number of substance P analogues for the antiserum was tested by radioimmunoassay using ¹²⁵I-Tyr⁸ substance P as tracer. The affinities of fragment 4-11, the substance P analogue H-Lys-Phe-Tyr-Gly-Leu-Met-NH₂ (CGP 15 898) and of substance P-free acid, which differs from substance P only in that it lacks the C-terminal carboxamide group, were respectively 2-, 10- and 4,000-fold less than that of the parent peptide.

Rat lumbar dorsal root ganglia were incubated with ³⁵S-methionine, homogenised, centrifuged and the radiolabelled peptides in the supernatant immunoprecipitated with anti-substance P serum. The immunoprecipitates were washed, redissolved by boiling in HPLC buffer and the radiolabelled peptides separated by reverse-phase HPLC (see legend to Fig. 1 for experimental details). In initial experiments designed to establish the specificity of the immunoprecipitation, washed immunoprecipitates were incubated overnight with a large excess (50 µg) of substance P in buffer A (see legend to Fig. 1). After centrifugation the supernatant was diluted with 1 ml buffer B and the labelled peptides separated by HPLC in the usual way. Elution by displacement with substance P and by

Rats were perfused with ice-cold Krebs–bicarbonate. Dorsal root ganglia L4–6 were dissected out, placed in 0.5 ml of incubation medium containing (mM) NaCl, 118; KCl, 4.5; CaCl_2 , 2.5; MgCl_2 , 1.15; HEPES (pH 7.5), 15; glucose 28 and 100 μCi ^{35}S -labelled L-methionine (Radiochemical Centre, 710 Ci mmol $^{-1}$), incubated with shaking at 37 °C under O_2 for 9 h, washed, held in 200 μl 2M acetic acid in a boiling waterbath for 10 min and homogenised. In experiments with cycloheximide ganglia were pre-incubated for 1 h with 0.1 mM cycloheximide, ^{35}S -methionine was then added and incubation was allowed to proceed for a further 9 h in the continued presence of cycloheximide. The homogenate was centrifuged and the supernatant lyophilised. The lyophilised samples were taken up in 250 μl buffer A (50 mM barbital buffer, pH 8.6 containing 1 mM EDTA, 0.5 mg ml $^{-1}$ L-methionine and 0.1% Triton X-100) and centrifuged. Aliquots (110 μl) of the supernatant were incubated for 16 h on ice with 20 μl buffer A (to which had been added 20 mg ml $^{-1}$ bovine serum albumin and 50 μg ml $^{-1}$ poly-lysine) and 10 μl anti-substance P serum or pre-immune serum. 14 μl goat anti-rabbit IgG serum (Miles) and 26 μl buffer A were then added and immunoprecipitates were allowed to form for a further 4 h at 4 °C. All sera were pretreated with phenylmethyl sulphonyl fluoride and iodoacetamide to inhibit protease activity 27 . Immunoprecipitates were washed three times with 1 ml buffer A then redissolved in 1 ml buffer B (0.1 M NaH_2PO_4 , 0.1 M H_3PO_4 , pH 2.1) containing 50 μg substance P, held in a boiling waterbath for 10 min and injected on to a 250 \times 4.6 mm column of Partisil 10 ODS using a 2 ml sample loop. After a loading phase of 3 min in buffer B the peptides were eluted with a gradient of acetonitrile in buffer B essentially as described by O'Hare and Nice 20 and terminating when the acetonitrile concentration reached 60% (v/v). Carrier substance P was detected by UV absorption at 225 nm and 10-drop fractions were collected for liquid scintillation counting in a Triton X-100 toluene-based scintillation fluid at 80% efficiency.

direct dissolution in HPLC buffer gave similar results, so, as the latter procedure was simpler, it was used routinely.

The ^{35}S -labelled material precipitated by anti-substance P serum separated as three well-defined peaks, one of which (peak III) coincided with authentic carrier substance P (Fig. 1*b*). None of these peaks corresponded with substance P sulfoxide which elutes at a point intermediate between peaks II and III. There was a lag phase before ^{35}S -methionine became incorporated into the substance P peak; no incorporation was detectable after 1 h but it became apparent at 2 h and continued to rise at 3 h and 8 h (Fig. 2). Incorporation of label into peak II followed a similar time course, whereas the radioactivity incorporated into peak I had reached a maximum at 2 h and thereafter remained essentially constant. There was no radioactivity in any of the three peaks when the anti-substance P serum in the immunoprecipitation step was replaced by serum taken from the same animal before immunisation (Fig. 1*c*). Incorporation of radiolabel into substance P was completely blocked by inclusion of 0.1 mM cycloheximide in the incubation medium (Fig. 1*d*).

In ganglia from 10-week-old rats which had been given 0.7 mg capsaicin on the second day of life 15 , incorporation into substance P (peak III) and into peaks I and II was respectively 12, 8 and 14% of that in normal animals (Fig. 1*e*). Neonatally-administered capsaicin causes degeneration of a population of small-diameter chemosensitive neurones 15,16 which are thought to use substance P as a neurotransmitter 3 . Animals treated in this way have severely reduced levels of substance P in the dorsal horn of the spinal cord 17 and in their dorsal root ganglia (unpublished observation). Morphometric studies of the ganglia and dorsal roots of these animals show that the population of small dark cells and of non-myelinated fibres is severely depleted while the population of myelinated fibres is slightly depleted 18 .

The substance P peak and also peak II were re-chromatographed on a 58 \times 1 cm column of Sephadex G-50 in phenol: acetic acid: water 1:1:1, containing 0.5% mercaptoethanol 19 . The substance P peak eluted as a single peak on Sephadex G-50 which coincided with ^{125}I -Tyr 8 substance P, confirming its identity with authentic substance P. Peak II eluted later than ^{125}I -Tyr 8 substance P on Sephadex G-50, suggesting that it is smaller than substance P. To test the possibility that peak II could have been formed artefactually from ^{35}S -substance P during extraction and chromatography, we added ^{125}I -Tyr 8 substance P to a ganglion homogenate and carried it through the complete procedure. The ^{125}I -Tyr 8 substance P treated in this way gave no extra peaks and so it seems likely that both peaks I and II represent peptides synthesised in the tissue. If peak II is a fragment of substance P it must be a C-terminal fragment as it contains ^{35}S -methionine. The retention time of peptides on reverse-phase supports has been shown to be broadly correlated with their hydrophobic amino acid content 20 . Thus fragments of substance P containing phenylalanine residues at both positions 7 and 8 may be expected to have similar or longer retention times than substance P. For example, fragment 4–11 is retained longer than substance P (Fig. 1*a*). As peak II elutes before substance P it could be a fragment in which one or both the phenylalanine residues has been lost. We are currently attempting to elucidate its structure.

The complete inhibition of substance P biosynthesis by cycloheximide (Fig. 1*d*) suggests that the peptide is synthesised by a conventional ribosomal mechanism. Substance P is released from nerve terminals 7,21,22 and so it is to be expected that, in common with other exported peptides 23,24 , substance P is synthesised on membrane-bound ribosomes. Consistent with this is the observation that the perikarya of the small dark neurones, in which substance P-like immunoreactivity is localised 8 and which are destroyed by capsaicin 15 , are replete with rough endoplasmic reticulum 25 . As it is thought that all peptides synthesised on membrane-bound ribosomes must be at least 40–60 residues in length and bear a hydrophobic N-terminal signal sequence 26 one would expect the undecapeptide substance P to be formed from a larger precursor. The latent period of 2 h between the addition of ^{35}S -methionine and the

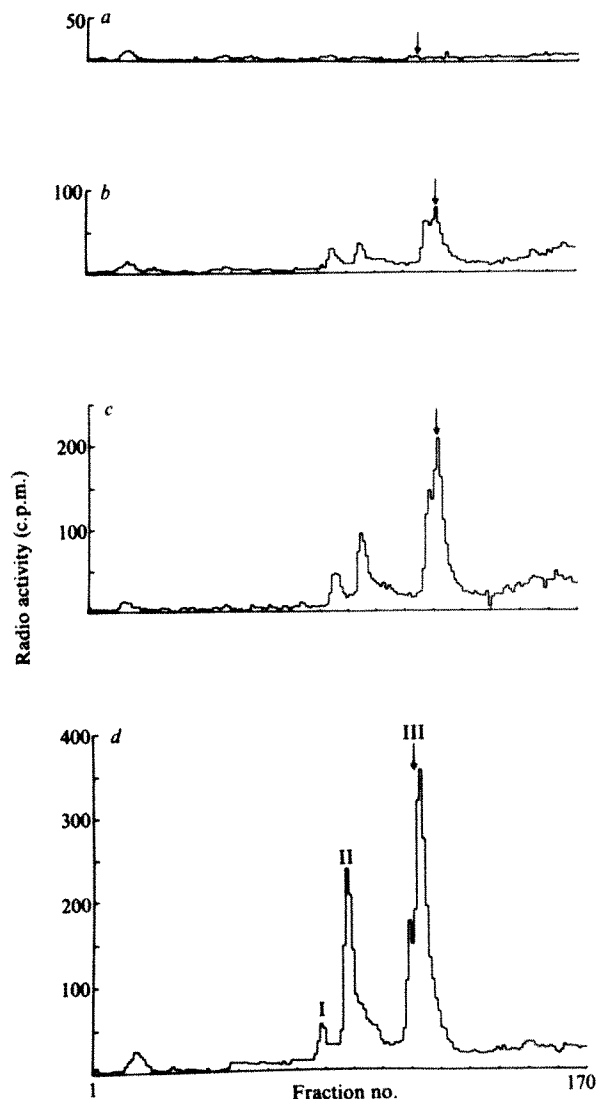

Fig. 2 HPLC of immunoprecipitates from rat dorsal root ganglia incubated with ^{35}S -methionine for 1, 2, 3 and 8 h. Method as in legend to Fig. 1 except that the entire supernatant from each homogenate was reacted with anti-substance P serum. Arrows denote position of carrier substance P.

appearance of the label in substance P (Fig. 2) may represent the time necessary for the processing of such a precursor. Note that the radioactivity incorporated into peak I had reached a maximum at 2 h and thereafter remained constant while incorporation into substance P continued to rise (Fig. 2). This is the behaviour expected of a precursor. Unfortunately the radioactivity incorporated into peak I in these experiments was insufficient to allow us to determine its size by subsequent chromatography on Sephadex G-50.

The present demonstration that isolated rat dorsal root ganglia are able to incorporate ^{35}S -methionine into substance P provides a system in which the synthesis and packaging of neurotransmitter substance P may be examined in detail. Using this system we have obtained evidence that substance P synthesis in dorsal root ganglia occurs by a ribosomal mechanism and that capsaicin may be a useful tool for the selective destruction of neurones responsible for this biosynthesis. We are continuing to investigate the possibility that substance P may be synthesised from larger molecular weight precursors.

We thank Ms S. Hyde for technical assistance, Dr E. Atherton for a gift of synthetic substance P and Dr H. Bittiger of Ciba-Geigy for a gift of CGP 15 898. This work is supported by a project grant from the MRC.

Enkephalin-, VIP- and substance P-like immunoreactivity in the carotid body

J. Wharton, J. M. Polak*, A. G. E. Pearce, G. P. McGregor, M. G. Bryant, S. R. Bloom, P. C. Emson†, G. E. Bisgard‡ & J. A. Will‡

The carotid body type I cell contains amines^{1–3} and has features, both morphological and cytochemical, which indicate that it may also produce a peptide^{4–6}. Many regulatory peptides are now known to be present in both central and peripheral tissues⁷. In the periphery these neuropeptides occur in both classical endocrine (APUD) cells and the neurones of the autonomic nervous system⁸. We have now investigated the possible presence of neuropeptides in the cat carotid body using both immunocytochemistry and radioimmunoassay. Met- and Leu-enkephalin-like material occurred in considerable quantities in carotid body extracts and enkephalin-like immunoreactivity was localised in type I cells. Both vasoactive intestinal polypeptide (VIP)- and substance P-like immunoreactivity was also present but was localised in nerve fibres distributed throughout the organ. These active neuropeptides are widely distributed in mammalian tissues, forming a diffuse regulatory system which now seems to include the carotid body.

Antisera to Met-, Leu-enkephalin, VIP and substance P were raised in rabbits and characterised for both radioimmunoassay (Table 1) and immunocytochemistry (Table 2). The carotid bodies and bifurcation of the common carotid arteries were removed from adult cats ($n = 25$) under pentobarbitone anaesthesia.

For immunocytochemistry, two methods of fixation were used. (1) The whole bifurcation, including the carotid body, was frozen in melting freon (Arcton), freeze dried, fixed in benzoquinone vapour for 3 h at 60 °C and embedded in paraffin wax⁹.

Table 1 Characterisation of antisera for enkephalin, VIP and substance P radioimmunoassays

Antiserum to	Carrier and coupler	Label	Sensitivity	Titre	Characterisation
Met-enkephalin	Bovine serum albumin (BSA) by glutaraldehyde	³ H-Met enkephalin	20–0.025 pmol <0.2% cross reactivity with Leu-enkephalin	1:1,500	C-terminal
VIP	BSA by carbodiimide	¹²⁵ I Chloramine-T method Pure porcine VIP	1 fmol per assay tube	1:320,000	C-terminal
Substance P	BSA or α -globulin by glutaraldehyde	¹²⁵ I Chloramine-T method Tyr ⁸ substance P	0.3 fmol per assay tube	1:8,000	C-terminal

(2) Tissue for liquid fixation was immersed in a 0.4% solution of benzoquinone in 0.01 M phosphate-buffered normal saline (pH 7.1–7.4) for up to 30 min at 4 °C (ref. 10). It was also rinsed several times in phosphate-buffered saline containing 7% sucrose and 0.01% sodium azide and cryostat blocks were prepared. Dewaxed and cryostat sections were stained by either the indirect immunofluorescence method¹¹ or the peroxidase–antiperoxidase (PAP) technique¹². Sections were incubated for 16–20 h at 4 °C, with antisera diluted in phosphate-buffered saline.

For radioimmunoassay the two carotid bodies from each cat were pooled and extracted twice with 500 μ l of 0.1 M acetic acid or with 500 μ l of water and 500 μ l of 0.1 M formic acid. The extracts were assayed in serial dilutions for VIP, substance P- and enkephalin-like immunoreactivity. The nature of the enkephalin-like material was examined using both column chromatography (Fig. 3) and thin layer chromatography¹³ (TLC). The carotid bodies were composed of clusters of cells separated by connective tissue and a rich vascular network. Large vessels, nerves and occasional ganglion cells were observed in the periphery of the organ.

Following incubation with either Met- or Leu-enkephalin antisera, immunoreactive cells were observed in the carotid body (Fig. 1). These cells were arranged in groups corresponding to the type I cell clusters. Immunostaining of serial sections revealed that the antisera stained the same groups of cells. No immunoreactive nerve fibres were seen in sections incubated with enkephalin antisera and type I cells were not stained by either VIP or substance P antisera.

An extensive network of varicose nerve fibres containing VIP-like immunoreactivity was observed (Fig. 2), associated principally with blood vessels and enkephalin immunoreactive type I cell clusters. VIP-like material also occurred in nerve fibres around the carotid arteries and in ganglion cells in the periphery of the carotid body. Fine nerve fibres immunostained with substance P antiserum were also distributed throughout the organ. The staining of each antiserum was completely abolished by preabsorption of the antiserum with its respective antigen (Table 2).

Significant amounts of VIP- (71.7 ± 18.4 pmol per g (\pm s.e.m.) $n = 5$), substance P- (54.6 ± 16.8 pmol per g) and enkephalin-like immunoreactivity (982.6 ± 203.8 pmol per g) were found in

the carotid body extracts. Examination of the extracts by TLC revealed that both Met- and Leu-enkephalin-like material was present, with between three and four times more Met- than Leu-enkephalin. On a BioGel column the enkephalin-like material eluted at the same position as ³H-labelled, synthetic Met-enkephalin (Fig. 3). In addition, a higher molecular weight immunoreactivity was detected which eluted with the void volume.

Our results reveal that, as in other organs⁸, the carotid body possesses an extensive network of nerve fibres containing substance P- and VIP-like immunoreactivity. The origin of these fibres is not entirely clear. Those in which VIP-like immunoreactivity occurs may, at least in part, arise locally, for scattered immunoreactive ganglion cells were seen in the periphery of the organ, whereas those containing substance P-like material may originate outside the carotid body. Substance P is reported to affect chemosensory activity in the cat carotid body¹⁴. However, the role of these peptides in this organ is unknown.

Fig. 1 Enkephalin-like immunoreactive type I cells in a 3- μ m thick section from a cat carotid body fixed in benzoquinone vapour ($\times 300$). Immunostained by the peroxidase–antiperoxidase technique with antiserum to Met-enkephalin (1:1,600 dilution).

Table 2 Characterisation of antisera for immunocytochemistry

Antiserum to:	REF	IF	Titre	Absorption (0.1–40 nmol per ml of diluted antiserum)					
				M-Enk	L-Enk	β -End	β -LPH	VIP	Sub P
Met-enkephalin	(497)	1:400	1:1,600	–(5)	–(40)	<(40)	<(40)	+	+
Met-enkephalin	(579)	1:200	1:1,000	–(5)	–(1)	<(20)	+	+	+
Leu-enkephalin	(493)	1:200	1:800	–(40)	–(5)	<(40)	+	+	+
Leu-enkephalin	(578)	1:200	1:1,000	–(5)	–(1)	–(20)	–(40)	+	+
VIP	(324)	1:300	1:2,000	+	+	+	+	–(0.1)	+
Substance P	(479)	1:500	1:4,000	+	+	+	+	+	–(5)

IF, Immunofluorescence technique¹¹; PAP, peroxidase–antiperoxidase technique¹²; REF, antiserum reference number. Controls included the application of antiserum preabsorbed with Met-enkephalin (M-Enk), Leu-enkephalin (L-Enk), β -endorphin (β -End), β -lipotropin (β -LPH), VIP or substance P (Sub P). +, No change in the intensity of the immunostaining; – (nmol ml^{–1}), minimum amount of peptide required to abolish the immunostaining; < (nmol ml^{–1}), amount of peptide required to reduce significantly the intensity of the immunostaining.

Fig. 2 Varicose nerve fibres containing VIP-like immunoreactivity, associated with a cluster of type I cells ($\times 415$). A 10- μ m-thick cryostat section incubated with antiserum to VIP (1:300 dilution) and immunostained by the indirect immunofluorescence technique.

Several peptides are known to be stored with amines in a single cell^{6,15-17} or neurone¹⁸⁻²¹, and it has recently been reported that adrenal chromaffin cells^{22,23} and their tumours^{22,24} contain enkephalin-like peptides in addition to catecholamines. The finding of enkephalin-like material in carotid body type I cells provides another example of the co-existence of amines and peptides in the same cell.

Both β -endorphin and β -lipotropin contain the molecular sequence of Met-enkephalin^{25,26}; thus, the partial abolition of the immunostaining by these peptides (Table 2), particularly that of Met-enkephalin, is not unexpected and may indicate the presence of a larger precursor molecule. The larger molecular weight, immunoreactive substance found in the extracts may be similar to that previously reported to occur in sympathetic ganglia²⁷.

It is well known that opiates depress respiration²⁸, but little information is available regarding their role in the carotid body. Opiates affect the release of central and peripheral neurotransmitters²⁹⁻³⁴ and the catecholamine content of adrenal medullary cells^{32,35}. It has been proposed that the two predominant catecholamines in the carotid body, dopamine and noradrenaline, modulate chemoreceptor discharge³⁶⁻³⁸. Thus, the association of amines and peptides may be of importance for the chemoreceptor properties of the carotid body.

Fig. 3 Gel permeation chromatography profiles of a cat carotid body extract (○) and ³H-labelled synthetic Met-enkephalin (■). Pooled formic acid and water extracts (1 ml) were applied to a BioGel P2 column (10 cm \times 1 cm) and eluted with a 100 mM sodium phosphate buffer (pH 7.4) containing 50 μ M bacitracin, at a flow rate of 1 ml per 3 min 200,000 c.p.m. ³H-Met-enkephalin was applied to the same column on a separate run, and detected in the effluent fractions by scintillation counting. V₀, Void volume; V_c, enkephalin.

We thank Professor J. R. Garrett for supplying some of the carotid bodies used in this study. This work was supported by a grant from the Council for Tobacco Research.

Selective inhibition of prostaglandin production in inflammatory exudates and gastric mucosa

B. J. R. Whittle, G. A. Higgs, K. E. Eakins, S. Moncada & J. R. Vane

Wellcome Research Laboratories, Langley Court, Beckenham, Kent BR3 3BS, UK

A major clinical problem encountered in the use of non-steroid anti-inflammatory drugs has been the high incidence of gastrointestinal irritation. The mechanisms underlying damage to the gastric mucosa evoked by these drugs are complex. The normal resistance of the gastric mucosa to the back-diffusion of gastric acid from the lumen into the mucosal tissue can be disrupted by topical administration of aspirin as well as several irritants such as ethanol, bile salts and detergents; this results in gastric mucosal damage¹. Such an action, however, cannot be the sole mechanism because many non-steroid anti-inflammatory drugs cause gastrointestinal damage when administered parenterally^{2,3}. It has been proposed that a reduction in prostaglandin biosynthesis by aspirin-like drugs⁴ in the gastric mucosa leads to a fall in local blood flow which, in turn, gives rise to areas of focal ischaemia ultimately developing into erosions⁵. However, a combination of the direct topical irritant actions and inhibition of prostaglandin formation can lead to a marked potentiation of gastric damage³. Such a situation is likely to be encountered in the clinical use of these compounds following

oral administration. We have investigated the relationship between gastric damage and inhibition of cyclooxygenase in the gastric mucosa following oral administration of anti-inflammatory compounds. For these studies, we have measured the *ex vivo* formation of prostacyclin (PGI_2), the major cyclooxygenase product in the rat gastric mucosa which, like other prostaglandins such as PGE_2 , has gastro-protective actions⁶. In the inflammatory exudate induced by carrageenin, PGE_2 predominates and has pro-inflammatory actions⁷. We have, therefore, investigated whether selective inhibition of prostaglandin production, assayed as PGE_2 -like activity, in the inflammatory exudate can be achieved *in vivo*. We report here that it can.

Previous studies have shown that cyclooxygenase inhibition *in vivo* prevents subsequent prostacyclin generation by the rat gastric mucosa *ex vivo*⁸. Strips of gastric mucosa (0.2–0.4 g) freed from underlying muscle were rapidly washed, chopped and incubated in buffer (50 mM Tris, pH 8.4, 1 ml) by vortex mixing (1 min, 22 °C). After centrifugation in a fixed-speed Eppendorf bench centrifuge (15 s at 9,000g) the supernatant was immediately tested for its ability to inhibit human platelet aggregation. This prostacyclin-like activity, which was characterised as described before⁸ and by the use of an antiserum which binds and inactivates prostacyclin⁹, was assayed against authentic prostacyclin.

Inflammatory exudates in male rats (200 g body weight) were induced and collected by the subcutaneous implantation of polyester sponges impregnated with carrageenin (20 mg ml⁻¹ in sterile saline). After 24 h, the sponges were removed, immersed in heparinised saline (5 ml) and squeezed until dry. The pros-

taglandin-like activity in acid-lipid extracts of these exudates was determined by bioassay on the rat superfused stomach strip, treated with a mixture of antagonists, and was expressed as PGE_2 equivalents¹⁰.

Erosion formation in the gastric mucosa was determined as described previously³. Food was removed from the individually caged rats immediately after initial drug administration. The animals were killed after 24 h and the incidence and severity of the erosions, which formed only in the secretory mucosa, was assessed. The compounds were suspended in Celacol solution (0.25% w/v carboxymethylcellulose) and the suspension adjusted to pH 5–6. Drugs were administered orally (0.1 ml per 100 g body weight), three times during the 24 h period, at the time of sponge implantation, 6 h later and again 3 h before removal of sponge or assessment of mucosal erosion formation and prostacyclin production.

The doses of the compounds given (see Fig. 1 legend) are all in the range causing 50–70% inhibition of inflammation, as determined by reduction in the oedema induced 3 h after the subplantar injection of carrageenin in the hind paw of rats^{11,12}. The dose causing 50% reduction of rat paw oedema (ED_{50}) was (in mg per kg) for aspirin, 130; sodium salicylate, 140; indomethacin, 2.7; flurbiprofen 0.4; naproxen, 5. The recently described dual inhibitor of cyclooxygenase and lipoxygenase, BW755C (3-amino-1-([*m*-(trifluoromethyl)-phenyl]-2-pyrazoline)¹² was administered in doses greater than those required for the anti-inflammatory actions (ED_{50} 11 mg per kg).

The clinically used compounds all reduced cyclooxygenase products in both the sponge and the gastric mucosa in these anti-inflammatory doses (Fig. 1B). Both aspirin and flurbiprofen seemed more active on cyclooxygenase in the gastric mucosa than in the inflammatory exudate. In contrast, sodium salicylate and BW755C, in doses causing a significant reduction in prostaglandins in the sponge, failed to inhibit mucosal cyclooxygenase activity. In further studies, the compounds were administered by a single oral dose and prostacyclin generation by the gastric mucosa was determined 3 h later. Sodium salicylate (200 mg per kg) and BW755C (100 mg per kg) again failed to prevent mucosal cyclooxygenase activity, whereas aspirin (50–200 mg per kg) and indomethacin (1.25–10 mg per kg) were potent inhibitors.

The activity of these compounds on gastric mucosal cyclooxygenase activity 3 h after subcutaneous injection was also investigated. Sodium salicylate (50–400 mg per kg) and BW755C (25–150 mg per kg) caused no significant inhibition of *ex vivo* prostacyclin formation, whereas aspirin (50–200 mg per kg), indomethacin (1.25–10 mg per kg), naproxen (2.5–20 mg per kg) and flurbiprofen (0.1–1 mg per kg) all caused dose-dependent reductions in prostacyclin production. This indicates that the potent inhibition of mucosal cyclooxygenase by these latter compounds is not simply a consequence of selective accumulation in the gastric mucosal tissue following administration of local high concentrations of these agents.

To investigate whether the failure to prevent prostacyclin formation was due to washout or dilution of the drug from the mucosa during the incubation procedures, gastric mucosal tissue from rats pretreated with sodium salicylate (200 mg per kg) was washed, chopped and incubated in buffer solutions containing sodium salicylate (10–100 $\mu\text{g ml}^{-1}$). Again, no inhibition of prostacyclin production could be detected. It has been suggested that the inhibition of prostacyclin production in rat aortic rings *in vitro* by indomethacin pretreatment can be reversed by washing and incubation of the tissue¹³. However, with our procedure and using gastric mucosal tissue, we have shown that pretreatment of rats with aspirin, indomethacin, naproxen and flurbiprofen always led to a potent inhibition of prostacyclin production *ex vivo*, suggesting little tissue washout or irreversible cyclooxygenase inhibition with these drugs.

The formation of gastric erosions following oral administration of those agents in anti-inflammatory doses, three times over 24 h, is shown in Fig. 1A, expressed in terms of an erosion

Fig. 1 Effect of oral administration of non-steroid anti-inflammatory agents on the induction of gastric erosions in rats (A), and prostaglandin E_2 -like activity in the sponge inflammatory exudate and the formation of prostacyclin (PGI_2) by the gastric mucosa *ex vivo* (B). The results are expressed as the mean \pm s.e.m. of *n* values. The changes in prostaglandin levels are given as % change compared with control levels, where an asterisk indicates significance ($P < 0.01$). The degree of gastric damage is expressed in terms of an erosion index. Drugs were administered orally three times over 24 h in the following doses (mg per kg): aspirin (200); sodium salicylate (200); indomethacin (4); flurbiprofen (0.5); naproxen (5); BW755c (100).

index. Indomethacin, flurbiprofen and naproxen induced a comparable degree of gastric erosion formation which paralleled their efficacy in inhibiting mucosal prostacyclin production in the doses used. Aspirin, however, was more active in inducing gastric damage in doses causing a similar mucosal cyclooxygenase inhibition to the other compounds. This may reflect the synergistic interaction³ between the topical irritation known to occur with aspirin^{1,2} and the inhibition of mucosal cyclooxygenase.

Interestingly, sodium salicylate, which failed to inhibit mucosal prostacyclin production in anti-inflammatory doses, caused little gastric damage. This finding is similar to observations in man that sodium salicylate produced far less gastrointestinal irritation than aspirin, as determined by faecal blood loss^{2,14}. Thus, topical irritation alone may not lead to pronounced gastric bleeding and erosion formation. Previously, it has been shown that systemically administered salicylic acid failed to prevent thromboxane A₂ formation in rat platelet-rich plasma, a situation in which washout of an active drug could not occur¹⁵. Furthermore, in our own studies on prostacyclin production *ex vivo* by rat isolated aortic rings, prior systemic administration of sodium salicylate (200 mg per kg, subcutaneously) failed to inhibit the vessel wall cyclooxygenase. This suggests that cyclooxygenase activity at the site of inflammation may be uniquely sensitive to inhibition by sodium salicylate and perhaps other drugs. An alternative, although unlikely explanation, would be that sodium salicylate could selectively inhibit PGE₂ but not prostacyclin formation, by an action beyond the cyclooxygenase, perhaps by affecting the subsequent transformation of the endoperoxide intermediate.

The dual cyclooxygenase and lipoyxygenase inhibitor, BW755C, which also failed to inhibit mucosal cyclooxygenase activity, similarly caused little gastric damage. This again gives support to a relationship between the production of gastric erosions and the inhibition of mucosal prostacyclin formation by anti-inflammatory drugs. The doses of BW755C used in this study were 5–10 times greater than the anti-inflammatory doses required to reduce carrageenin foot paw oedema and white cell migration into sponges¹², suggesting a good therapeutic ratio for this experimental compound. Further, the dual inhibition of the two major pathways of arachidonate metabolism is likely to be a beneficial property in the control of leukocyte migration and inflammation¹².

Although cyclooxygenase enzyme preparations from tissues such as spleen, kidney and brain have shown differential sensitivities to some compounds *in vitro*¹⁶, the present findings clearly demonstrate that some non-steroid anti-inflammatory drugs can selectively inhibit prostaglandin biosynthesis in different tissues *in vivo*. The development of anti-inflammatory compounds which fail to inhibit cyclooxygenase in the gastric mucosa and lack topical irritancy seems to be a rational approach to obtaining clinically well-tolerated drugs.

We thank Mr K. Mugridge and Ms J. Walker for technical assistance and Drs. C. V. Denyer and F. C. Copp for preparing BW755C.

Lentil lectin effectively induces allotransplantation tolerance in mice

Ivan Hilgert, Václav Hořejší, Pavla Angelisová & Hana Křištofová

Institute of Molecular Genetics, Czechoslovak Academy of Sciences, Prague 4, Czechoslovakia

The interaction of lectins with carbohydrate receptors on the plasma membrane of eukaryotic cells results in a wide variety of biological effects¹. One effect which has been extensively studied is the stimulation of lymphocytes to blastogenesis and proliferation. High doses of concanavalin A (Con A) and phytohaemagglutinin (PHA) have been shown to activate *in vitro* regulatory cells capable of suppressing proliferation of other cells in the culture^{2,3}. However, Con A and PHA treatment were used effectively to prolong the survival of skin and heart allografts^{4–8} before it was recognised that some lectins have an activatory effect on suppressor cells *in vitro*. A possible explanation of these tolerogenic effects is the activation of specific suppressor cells. In this letter we have compared systematically various lectins differing in their carbohydrate specificity and mitogenicity in relation to their ability to induce prolonged skin allograft survival in mice with the aim of selecting the most effective lectin treatment schedule. Some preliminary results of this study have been mentioned in a recent review⁹.

All lectins used were purified by affinity chromatography and were devoid of any electrophoretically detectable contaminants. Con A, pea lectin (PsA), lentil lectin (LcA) and sweet pea (*Lathyrus odoratus*) lectin (LoA) were prepared by affinity chromatography on Sephadex G-100 (refs 10–12), soybean lectin (SBA) by affinity chromatography on *N*-acetyl-D-galactosaminyl polyacrylamide gel¹³, *Erythrina indica* (EiA) lectin on α -D-galactosyl polyacrylamide gel¹⁴, wheat germ lectin (WGA) on *N*-acetyl- α -D-glucosaminyl polyacrylamide gel and scarlet runner (*Phaseolus coccineus*) seed lectin (PcA) by affinity chromatography on fetuin-Sepharose. Unless otherwise stated, mouse strain combination B10.D2 \times B10.D2(M504) (abbreviated to M504) was used; the histocompatibility difference between these strains lies in their H-2D regions^{15,16}. In other experiments another strain combination was used (B10.A \times C57BL10ScSn) (abbreviated to B10) these strains differing in all regions of the H-2 locus. To study the specificity of tolerance induced by the lectin treatment and B10.D2 skin graft in M504 recipients, third-party grafts from BALB/c mice were used. This strain is identical with the original donor strain (B10.D2) at the H-2 locus but differing at the multiple non-H-2 loci. In all cases, both recipients and donors were females.

Comparisons were made using three different time schedules of LcA injection relative to time of skin allografting (Fig. 1). In schedules where all 10 doses of the lectin were given before grafting or 5 doses were given before and 5 after grafting, allograft survival was not essentially affected. In contrast, 10 doses (each 250 μ g) given after grafting made 2 out of 6 animals long-term tolerant (skin graft survival >100 days). Further improvement of graft survival time could be achieved by increasing the lectin dose to 500 μ g and total number of doses given to 20. In these conditions allografts of all LcA-treated recipients survived for more than 100 days (Fig. 2). These long-term surviving grafts did not show any macroscopically visible signs of rejection.

The effect of different lectins was compared using this optimum schedule (20 doses of 500 μ g, all given intraperitoneally (i.p.) after transplantation) (Fig. 2). (The doses of Con A and WGA, however, were only 250 μ g because of their toxicity at higher doses.) WGA, SBA and EiA did not induce long-term

Fig. 1 Survival of B10.D2 grafts in M504 recipients treated with 10 doses of LcA (250 µg, i.p.). Comparison of three different time schedules of LcA administration. Inset shows the schedule of treatment (intervals between the doses were 48 h). Test transplantation (TR) is always on day 0. Skin grafts prepared from tail skin ~0.5 cm² in size were transplanted onto the backs of the tested recipients²⁵. Grafts with irreversible necrotic changes over their whole area were considered rejected.

skin allograft survival (date not shown), Con A, PcA and LoA induced tolerance only occasionally, whereas PsA induced long-term tolerance in about 50% of recipients and LcA in 100% of recipients. The LcA treatment did not seem to have any observable harmful side effects on the animals.

The efficiency of the most effective lectin, LcA, could be still increased by administering some doses intravenously (i.v.) (1st, 3rd, 5th and 7th dose given i.v., all others i.p.); in this situation, 20 doses of only 250 µg each induced long-term allograft survival in 90–100% of recipients. Long-term tolerance in 90–100% of recipients was induced also if the most effective lectin treatment started on the third day after transplantation; when it started 5 days after skin grafting, long-term tolerance was still induced in 50% of the cases.

Transplantation of a second B10.D2 allograft (no treatment) into recipients surviving with the first graft after 100 days as a result of LcA treatment led almost always to rejection of the

Fig. 2 Survival of B10.D2 grafts in M504 recipients treated with 20 x 500 µg i.p. doses of different lectins. The dose of Con A was 250 µg due its toxicity in higher doses. Inset time schedule of lectin treatment.

second graft in 12–20 days; the primary graft remained unaffected. This indicates either a rather unstable nature of the lectin-induced tolerance even 100 days after primary graft transplantation, or the occurrence of some form of protection of the first graft in the host. Although unexpected, this result is not unprecedented; similar effects were observed in the case of neonatally-induced tolerance (G. A. Voisin, personal communication) and in the case of liver extract-induced tolerance¹⁷, where the stability of tolerance was shown to increase progressively with time elapsed after transplantation (from 50th to 150th day). Studies on the possible stabilisation of lectin-induced tolerance with time and by increased lectin dose are now in progress in our laboratory.

Third-party test allografts (BALB/c) transplanted into recipients bearing a B10.D2 graft for >100 days resulted in a rapid rejection of the BALB/c graft (11–14 days), usually accompanied by a delayed rejection of the primary B10.D2 graft (in 15–30 days).

Therefore, the mechanism of this type of tolerance is not yet clear, but the lectin certainly does not act through nonspecific damage or suppression of immunological reactivity of the recipient as evidenced by the rapid rejection of third-party grafts. It is of interest that the lectin treatment is remarkably efficient even when it is started several days after transplantation; this indicates that the lectin might be interacting with the antigen-sensitised lymphocytes.

Fig. 3 Survival of B10.A grafts in B10 recipients treated with LcA. The lectin (1 mg in 0.5 ml phosphate buffered saline) was given i.p. daily starting with the day of transplantation (day 0) until rejection; the doses on days 1, 3, 5, 7 and 9 were given i.v. For other experimental details see Fig. 1 legend.

All lectins with detectable tolerogenic activity (except PcA) have similar carbohydrate specificity (α -D-Man, α -D-Glc) and are structurally fairly similar (a Con A-like group of lectins)¹⁸. Lectins with similar carbohydrate specificity and probably also similar structure are present in seeds of many other plants belonging to the Fabaceae family¹⁹; it is quite possible that some of these poorly studied lectins might be even more effective tolerance inducers than LcA.

The primary target of action of LcA and similar lectins is probably a specific carbohydrate receptor or class of receptors on the cell surface. However, the plant lectins might also act by mimicking the action of (or competing with) some endogenous lectin-like regulatory substances (for example, lymphokines).

The LcA treatment of recipients compares well with other treatments used for induction of adult transplantation tolerance (spleen extract alone²⁰ or in combination with hydrocortisone acetate²¹, antilymphocyte serum²²) at least in the mouse strain

combination tested (B10.D2×M504); unlike LcA, none of these treatments was able to induce long-term (permanent) survival of skin grafts in 100% of the recipients. Other highly effective ways of induction of transplantation tolerance in mice, for example combined treatment with several immunosuppressive drugs²³ or cyclosporin A treatment²⁴, were demonstrated in other strain combinations and thus direct comparison with LcA effects is not possible at present. Our recent results indicate that LcA is highly efficient in prolonging allograft survival and in inducing tolerance in a strain combination with a strong H-2 barrier (B10.A×B10) (Fig. 3).

In conclusion, LcA is possibly one of the most effective substances known so far (in combination with skin graft as a source of specific antigens) for inducing adult transplantation tolerance in mice. Experiments are now in progress to determine what maximal histocompatibility barrier can be overcome by LcA treatment alone or in combination with other immunosuppressive drugs, whether LcA is also effective in other animal species, the details of induction mechanism and maintenance of this type of tolerance.

The human 'T' genetic region of the HLA linkage group is a polymorphism detected on lectin-activated lymphocytes

Ephraim Gazit

Tissue Typing Laboratory, Chaim-Sheba Medical Center, Tel-Hashomer Hospital, Israel

Cox Terhorst & Edmond J. Yunis

Divisions of Tumor Immunology and Immunogenetics, Sidney Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts 02115

The major histocompatibility complex of the mouse, H-2, comprises 12 loci which are grouped into regions and subregions¹. Present data indicate that to the 'right' of the H-2D there are nine loci clustered into one region, the 'T region'. These loci are designated Qa-1, Qa-2, Qa-3, Qa-4, Qa-5, H-2T, H-31, H-32, TLa (ref. 2). The loci in the 'T region' may, in fact, be part of the H-2 complex. This notion is supported by the fact that gene products of the TLa, Qa-2 and Qa-3 loci share some molecular properties with H-2 products: a two-polypeptide chain complex with a common determinant of molecular weight 12,000 β_2 -microglobulin and a variable heavy chain of MW 45,000 (ref. 3). Recent reports suggested the possible existence of human analogues to the gene products of the murine 'T region'. Antigenic structures, similar but not identical with HLA-A, -B and -C antigens, were recently isolated from the human lymphoblastoid T-cell line MOLT4 (refs 4, 5). These reports presented evidence for the existence of a β_2 -microglobulin or a β_2 -microglobulin-like molecule, Bt, associated with a polypeptide chain of MW ~ 45,000. However, it remains to be determined whether these structures are equivalent to the mouse Qa-1, Qa-2 or TLa gene products. We now report the identification of human alloantisera that react with cell-surface determinants expressed on mitogen-activated T lymphocytes but not expressed on resting T cells. Antigen blocking and modulation techniques were used. The alloantigens identified (HT) are different from the classical HLA-A, -B, -C and -DR antigens but are associated with β_2 -microglobulin. These determinants are encoded by genes in the HLA-A region and may represent the human counterpart of the TLa region determinants of the mouse^{1–3}.

We have screened 200 sera obtained from women with a history of multiple pregnancies. The sera were exhaustively absorbed with platelets and were shown to be non-reactive with HLA-A, -B and -C antigens carried by the resting peripheral blood lymphocytes from two different individuals: D.W., whose HLA phenotype is A1, A3, B8, B18, Cw2, DRw3, DRw5; and E.G., whose HLA phenotype is A2, A3, B14, B37, Cw6, DRw1 and DRw5. Lectin (phytohaemagglutinin (PHA) or concanavalin A (Con A))-activated lymphocytes obtained from these two individuals were used to screen the platelet-absorbed pregnancy sera. Two antisera, SF48 and K, were found to react exclusively with the activated lymphocytes by a cytotoxicity score of 40–60%.

The sera were subsequently absorbed with resting lymphocytes from either D.W. or E.G. by a tray microabsorption technique (200×10^6 lymphocytes per ml) and the sera were found to retain their reactivity with mitogen-activated lymphocytes only (Table 1). The sera were then tested in a random panel of activated lymphocytes and gave 11/23 (47.8%) and 8/23 (34.8%) positive reactions with SF48 and K, respectively. The 2×2 tables between the HLA assignment of the panel and the cytotoxic reactions of these two sera are given in Table 2. Significant associations were found for reactivities of serum SF48 with HLA-A3 ($P = 1.77 \times 10^{-6}$) and serum K with HLA-A1 ($P = 1.24 \times 10^{-3}$). Having serologically ruled out the existence of antibodies against HLA antigens, we tested these sera in a selected panel of HLA-A1 or HLA-A3 phenotypes and demonstrated that lectin-activated lymphocytes in three out of five HLA-A1 individuals reacted with K, and five out of seven HLA-A3 individuals reacted with SF48 (Table 3). In addition, three T-lymphoblastoid cell lines were tested with SF48 and K antisera: HSB-2 (HLA-A1, A2, B17, Bw44), RPMI-8402 (HLA-A1, A29, B18, B16) and MOLT-4 (HLA-A1, A10). Only MOLT-4 was able to absorb both the SF48 and K reactivity directed against D.W. and E.G. test cells, but did not remove the reactivity of HLA-A3 antiserum. MOLT-4, in contrast to the activated lymphocytes (see Table 1), reacted with 100% cytotoxicity, indicating that all MOLT-4 cells carry the antigen(s) detected by SF48 and K. It is of interest that the MOLT-4 cells have recently been shown to contain antigenic structures different from HLA-A and -B but associated with β_2 -microglobulin^{4,5}. These experiments, *per se*, exclude the possibility that the K and SF48 antigenic determinants represent a presentation of HLA-A, -B or -C antigens that are unique to lectin-stimulated lymphocytes.

To examine the remote possibility that HLA antibodies were not removed from SF48 and K sera after sequential absorptions

Table 1 Serological characterisation of PHA- and Con A-activated lymphocytes

Donor	Cell tested	Pretreatment	Microcytotoxicity scores with

The platelet-absorbed pregnancy sera SF48 and K were tested in a microcytotoxicity assay, using fluorescein diacetate¹². The numbers are estimates obtained in the two-stage microlymphocytotoxicity assay: 1, 2, 4, 6 and 8 denote 0%, 10–25%, 25–50%, 50–75% and 75–100% cytotoxicity above background, respectively. Peripheral blood lymphocytes were separated on a Ficoll-Hypaque density gradient, washed three times and cultured at 37 °C in RPMI-1640 containing 20% pooled human serum, penicillin, streptomycin and L-glutamine. The cells were cultured for 5 d at a cell density of 1×10^6 per ml with either 5 μ g Con A per ml or 1.201 PHA per ml. E⁺ and E⁻ lymphocytes were obtained after rosetting with neuraminidase-treated sheep red blood cells¹³. Absorptions were carried out with 50,000 cells per μ l of serum in the case of E⁺ and E⁻ cells and with 200,000 cells per μ l of serum when whole lymphocytes were used. Blocking was done as previously published¹⁴. Turkey and goat-anti- β_2 -microglobulin (β_2 m) sera were prepared by multiple injections (in complete Freund's adjuvant) of β_2 -microglobulin purified from the urine of kidney transplant patients¹⁵. Turkey and rabbit (C91) anti-p29,34 (anti-Ia) sera were prepared in a similar way. The p29,34 antigens were isolated from a highly purified plasma membrane preparation¹⁶ of the B-lymphoblastoid cell line JY after solubilisation in deoxycholate by lentil lectin affinity chromatography and anti- β_2 -microglobulin immunoabsorbent column chromatography as described earlier^{17,18}. All sera were heat inactivated before use.

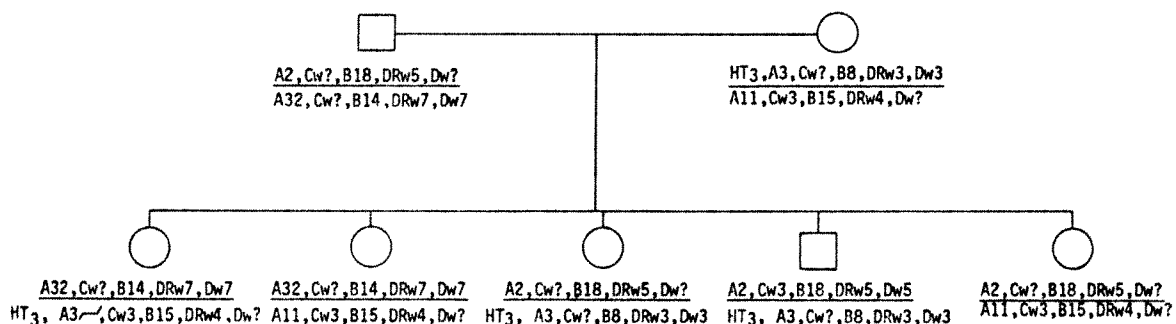

Fig. 1 A family (family F) using a microcytotoxicity assay with serum SF48. The first sibling on the left is an HLA-A/B recombinant. This family was recently discovered and has been thoroughly studied in the 8th International Histocompatibility Workshop.

with pooled platelets and resting lymphocytes from the same donor of the activated lymphocytes, the following experiment was carried out. Activated lymphocytes from individuals who were: (1) HLA-A3⁺, SF48⁺, (2) HLA-A3⁺, SF48⁻, and (3) HLA-A3⁻, SF48⁻, were used in cross-absorption experiments, in which HLA alloantisera defining HLA-A3 and SF48 were tested. The results obtained indicated that HLA-A3⁺, SF48⁺

cells absorbed all activity from both types of antisera, HLA-A3⁺, SF48⁻ cells absorbed the HLA only and HLA-A3⁻, SF48⁻ cells absorbed neither of them (Table 4).

Second, antigenic modulation experiments were carried out using a rabbit anti-HLA heavy chain serum, C41. For the preparation of the rabbit anti-HLA heavy chain antiserum (C41), the larger polypeptide chain of papain-solubilised HLA-

Table 2 2×2 tables of association between HLA assignment of the panel and SF48 and K reactivity

	HLA-A3		K	HLA-A1	
	+	-		+	-
	+11	1		4	4
SF48	- 0	11		- 0	15
$P(\text{Fisher}) = 1.77 \times 10^{-6}$				$P(\text{Fisher}) = 1.24 \times 10^{-3}$	

HLA assignment of the screening panel compared with the reactivity to SF48 and K. The panel consisted of unrelated randomly chosen individuals ($n = 23$). The P value reflects the probability of a random association between the two variables under study.

A2 antigen was isolated from the B-lymphoblastoid cell line RPMI-4265 as described elsewhere⁶. The resulting antibody had a cytotoxicity titre of 1:100 using lymphoblastoid cell lines JY and 1:10 using resting peripheral lymphocytes. This antibody also reacted with Daudi cells which agrees with studies showing that Daudi cells express the heavy chain of HLA antigens on their surface⁷. In addition, two monoclonal HLA heavy chain antibodies (w6/32 and w34/28)⁸ were obtained commercially (from Accurate Chemical Corporation). Both resting and mitogen-activated lymphocytes were incubated with varying dilutions of these antisera for periods extending to 6 h. The lymphocytes were then washed and retested with the three anti-HLA heavy chain sera or with alloantibodies. Results showed that prior incubation of the activated lymphocyte with HLA heavy chain antibody, in the absence of complement, did not suppress HLA heavy chain determinants on retesting in a subsequent cytotoxicity assay. Indeed, all three HLA heavy chain antibodies, in addition to HLA-A1, HLA-A3, SF48 and K antisera, were still capable of lysing the test cells. However, antigenic modulation of activated lymphocytes from E.G. (A2, A3, B14, B37, Cw6) with HLA-A3 antibody (kras) eliminated subsequent lysis mediated by HLA-A3 and complement, but not lysis by SF48 and complement. Following antigenic modulation with HLA-A3 antibody in control experiments, subsequent lysis was positive with HLA-A2 and HLA-B14 antisera but negative with HLA-A1 antiserum and complement. These results indicated that SF48 and HLA-A3 membrane antigens are expressed independently on the cell surface of mitogen-activated lymphocytes.

As Ia antigens are expressed on activated T cells⁹⁻¹¹, we designed experiments to determine whether or not the reactivity in SF48 and K alloantisera is due to antibody directed against DRw antigens. Blocking experiments were carried out by pretreating Con A- and PHA-activated T cells with a turkey

anti-Ia (p29, 34) serum and subsequently testing K and SF48 alloantisera in a microcytotoxicity assay¹² (Table 1). This turkey antiserum, which does not bind mammalian complement, completely eliminated the reactivity with eight specific anti-DRw allosera (data not shown) and a rabbit anti-p29,34 serum C91 (Table 1). However, the reactivity of K and SF48 alloantisera was not affected by prior blocking with the turkey anti-Ia serum. These results indicated that the reactivity of K and SF48 alloantisera is not directed against DRw Ia-like determinants on the activated lymphocytes.

Taken together, these experiments indicated that PHA- and Con A-activated lymphocytes contain antigenic determinants that are associated with β_2 -microglobulin but are different from the classical HLA-A, -B and -C antigens. Serological studies on a random panel showed that these determinants are genetically related to the -A1 and -A3 alleles of the HLA-A locus, but as shown in Table 3, some false negative and false positive assignments can be made, indicating a serological independence of the K and SF48 specificities from the HLA-A1 and -A3 determinants. Genetic analyses of four families with informative segregation for both SF48 and K in microcytotoxicity assays indicated linkage of these determinants with HLA. One of these families (Fig. 1) demonstrated linkage between the locus coding for HLA-A and that coding for the antigenic determinant(s) recognised by SF48 alloantiserum.

Table 4 Cross-absorption with PHA-activated lymphocytes

Antisera	Absorbed with:		
	A3 ⁺ SF48 ⁺	A3 ⁺ SF48 ⁻	A3 ⁻ SF48 ⁻
Anti-HLA-A3	1	1	8
SF48	1	6	6
Testing cell = A3 ⁺ SF48 ⁺			

All absorptions and cytotoxicity scoring are as in Table 1. HLA phenotype of activated lymphocytes from the A3⁺, SF48⁺ individual D.W. is A1, A3, B8, B18, Cw2, from the A3⁺, SF48⁻ individual J.S. is A3, A24, B7, B17, and from the A3⁻, SF48⁻ individual D.F. is A11, Aw32, B14.1, B15.1, Cw3, Bw6.

We conclude that alloantisera K and SF48 detected antigenic determinants of a new polymorphic locus closely linked to the HLA-A locus on chromosome 6 in man. We have tentatively named it HT (human T locus) and have described two possible alleles, HT-1 and HT-3, based on the high degree of association and/or linkage disequilibrium with HLA-A1 and HLA-A3.

We thank Dr Richard J. Mahoney for reviewing the manuscript, Ms Rita Zimmermann and Kenneth LeClair for technical assistance and Ms K. Broadstreet and Mr B. Baillie for preparing the manuscript. This research was supported by NIH grants (AI 15066, CA 06516, CA 20531 and CA 19589 and by the Northeast Regional Red Cross Blood Program, Boston, Massachusetts.

T-cell-derived helper factor allows *in vivo* induction of cytotoxic T cells in *nu/nu* mice

Hermann Wagner, Conny Hardt, Klaus Heeg, Martin Röllinghoff & Klaus Pfizenmaier

Institut für Medizinische Mikrobiologie der Johannes Gutenberg-Universität Mainz, Hochhaus am Augustusplatz, D-6500 Mainz, FRG

T-cell immunocompetence and diversity are thought to be generated in the thymus^{1,2}. This view is based on the findings that (1) T-cell ontogeny is thymus dependent^{3,4}, (2) the major histocompatibility restrictions of T-cell interactions are phenotypically related to the H-2 type of the thymus⁵⁻⁹, and (3) the phenotypic manifestation of H-2-linked immune responsiveness parallels the restriction elements selected in thymus¹⁰⁻¹². However, it is unclear whether pre-thymic cells programmed to develop into T cells do already express a receptor diversity, also whether pre-thymic cells have the potential to react against self-antigens, and whether the mechanism of self-tolerance is initiated in the thymus by either elimination or suppression of self-reactive clones. If it were possible to confer on pre-thymic cells antigen-specific effector functions, the impact of the thymus on the generation of T-cell diversity and function could be analysed in more detail. In mice, the nude mutation lacks a functioning thymus^{13,14}; *nu/nu* mice possess a thymic rudiment which is epithelial in the embryo¹⁵ and a fibrous, cystic remnant in adult^{15,16}; this remnant is not populated by lymphoid cells¹⁵⁻¹⁷. At present, the absence of immunocompetent T cells in *nu/nu* mice is explained by a lack of thymic differentiation and maturation of pre-thymic cells (reviewed in ref. 13). Here we report that injection of allogeneic stimulator cells plus a Lyt 1 T-cell-derived helper factor^{18,19}, termed interleukin 2 (for the system of nomenclature, see ref. 20) allows lymphocytes of *nu/nu* mice to differentiate *in vivo* into alloreactive cytotoxic T lymphocytes (CTLs).

The rationale of our experiments is based on the following observations. Murine thymocytes generate *in vitro* little, if any, cytolytic activity in response to otherwise immunogenic stimuli. However, in the presence of interleukin 2, the cytolytic response generated to alloantigens is almost equal to that normally existing in peripheral T cells²¹. More recently, we noted that even peanut-agglutinin-positive thymocytes, assumed to be cortical cells and thus immunoincompetent²², contained high numbers of CTL precursors which develop into CTLs in the presence of interleukin 2 (ref. 23). This suggested that the limiting factor in antigen-induced cytotoxic responses of immature thymocytes is not a lack of antigen-reactive CTL precursor cells, but a relative lack of cells producing interleukin

2. As cortical thymocytes had been assumed to be immunoincompetent, but exhibited immunocompetence in the presence of interleukin 2 (ref. 23), it was of interest to test whether in the presence of alloantigen interleukin 2 could also confer T-cell competence to lymphocytes in thymus-deficient *nu/nu* mice. The second observation relevant in this context was that sera of thymus-bearing normal mice inhibited the *in vitro* activity of the Lyt 1 T-cell-derived interleukin 2. In contrast, sera from athymic mice supported its functional activity (C.H., unpublished data). It was thus reasonable to assume that on injection of interleukin 2 into athymic mice, its functional activity would be maintained. Consequently, we tested whether *in vivo* T-cell precursors of *nu/nu* mice would respond to alloantigens, provided semi-purified¹⁸ interleukin 2 was simultaneously injected.

Of the various experimental approaches tested so far, reproducible results were obtained using the following protocols. Protocol A: On two consecutive days, 2×10^7 irradiated (2,000 rad) C57BL/6 mouse-derived splenic stimulator cells (H-2^b) were injected into the hind footpad of BALB/c *nu/nu* mice. Starting at the same time, the mice received, subcutaneously into the hind footpad, 100 μ l of helper factor twice a day for 3 d. Protocol B: BALB/c *nu/nu* mice received at the same time intervals the same dose of stimulator cells and helper factor intravenously. At day 5, the mice were killed and their lymph node cells and splenic cells tested for cytotoxic activity towards H-2^b, H-2^k and H-2^d target cells. As can be seen from Table 1, both protocols resulted in the *in vivo* induction of antigen-specific cytolytic effector cells within the spleen cells of *nu/nu* mice.

We subsequently defined a more convenient protocol for generating alloreactive cytolytic effector T cells from *nu/nu*-derived precursor T cells. Because the Lyt 1 T-cell-derived factor is generated in the course of a mixed lymphocyte culture, we reasoned that the factor ought also to be produced in the course of a graft-versus-host reaction (GvH) *in vivo*. Moreover, Piguet and Vasalli²⁴ recently reported that *nu/nu* mice are apparently able to reject up to 6×10^7 grafted allogeneic cells, provided the grafted cells contained T lymphocytes. This apparent paradoxical finding was not pursued further by the authors. One explanation for this is that during a T-cell-dependent GvH reaction induced in nude mice, helper factor may be produced *in vivo*, which in turn would allow *nu/nu* T-cell precursors to respond to the immunogenic stimulus represented by the grafted allogeneic cells.

In agreement with the results of Piguet and Vasalli²⁴, we noted that 8–9 d after injection of 6×10^7 allogeneic spleen cells the recipient *nu/nu* mice had rejected the grafted cells, that is, no grafted cells were detectable by serological techniques in the spleen of the killed recipient *nu/nu* mice (data not given). More interestingly, 8 d after grafting, the recipient *nu/nu* spleen cells exhibited low but significant cytolytic activity with specificity for target cells expressing the same alloantigen as the grafted cells (Table 2). The magnitude of cytolytic activity could be enhanced by restimulation of the *nu/nu* spleen cells *in vitro* in the presence

Table 1 *In vivo* induction of antigen-specific cytolytic effector cells in thymus-deficient nude mice

Protocol used	Cells tested	EL4 (H-2 ^b)			% Specific lysis of target cells			P815 (H-2 ^d)		
		500:1	120:1	30:1*	500:1	120:1	30:1	500:1	120:1	30:1

	spleen	22	10	2	–1	3	2	2	–2	1

Protocol A: BALB/c nude mice (Bomholtgaard) were injected on two consecutive days, each with 2×10^7 C57BL/6-derived, irradiated (2,000 rad) splenic lymphocytes into the hind footpad. Simultaneously, the mice were injected at the same site, twice a day for 3 d, with 100 μ l semi-purified T-helper factor¹⁸. Protocol B: at identical time intervals, BALB/c nude mice received intravenously the same dose of stimulator cells and T-helper factor as in A. After 5 d, the mice were killed and single cell suspensions were prepared from either lymph node cells (LN) or spleen cells¹⁸. Lymphocytes were assayed for cytolytic activity in a 4-h standard ⁵¹Cr-release assay towards EL 4(H-2^b), LS (H-2^k) and P815 (H-2^d) target cells essentially as described elsewhere¹⁸. For each population tested, a dose-response curve was established. Per cent specific ⁵¹Cr-release was calculated according to the formula described previously¹⁸. Background lysis of the target cells was less than 23%.

* Ratio of effector cells to target cells used in the 4-h ⁵¹Cr-release assay.

Thymus-deficient BALB/c mice received intravenously either 6×10^7 C57BL/6 mouse (H-2^b) or CBA mouse (H-2^k) splenic lymphocytes. After 8 d, the mice were killed and single cell suspensions were prepared from the spleen cells. According to the results obtained in complement-dependent cytotoxicity assay using anti-H-2^k, anti-H-2^d, anti-H-2^b antisera⁸, more than 95% of the spleen cells were BALB/c-mouse derived. One part of the spleen cells was assayed for cytotoxicity against ⁵¹Cr-labelled P815 (H-2^d), EL4 (H-2^b) and LS (H-2^k) target cells in a 4-h ⁵¹Cr assay. The remaining spleen cells (4×10^6) were cultured *in vitro* for an additional 5 d in the presence of irradiated stimulator cells (1×10^6) plus 50 μ l semi-purified T-helper factors¹⁸ in conditions described previously^{18,23}. Thereafter, the cells were treated with normal AKR serum plus complement or with monoclonal anti-Thy 1.2 antibody (derived from clone F7D5; Olac) plus C. The surviving cells were assayed for cytotoxicity against the target cells listed. Background lysis of the target cells during the 4 h ⁵¹Cr-assay did not exceed 20%.

* Ratio of effector to target cells. ND, not done.

of T-helper factor (Table 2). As the cytolytic activity was abrogated after treatment of the cells with anti-Thy 1 antisera plus complement (Table 2), we concluded that the antigen-specific cytolytic activity generated *in vivo* was carried out by *nu/nu* mouse-derived T cells.

Despite the presence of some Thy 1-positive cells²⁵ and possibly ectopic thymus tissue²⁶, normal *nu/nu* mice exhibit no T-cell functions^{27,28}. Although an increased *in vitro* development of Thy 1 antigen on the surface of nude spleen cells has been described following treatment with thymus extracts^{29,30}, culturing on thymus reticuloendothelial cell monolayers³¹ or exposing the cells to neuraminidase³² or poly(AU) (ref. 33), appearance of the Thy 1 surface antigen should only be equated with T-cell differentiation if T-cell function is demonstrated. This has been achieved recently by Gillis *et al.*³⁴. Accordingly, lymphocytes from *nu/nu* mice were able to differentiate *in vitro* into alloreactive CTLs, provided the cells were cultured in the presence of stimulator cells plus T-cell growth factor (TCGF). Obviously, these *in vitro* results almost parallel our *in vivo* findings described here.

Our results are relevant to two issues. First, a well-characterised lymphokine^{18,19} is now shown to be active *in vivo* in restoring T-cell immune functions in *nu/nu* mice. Second, the data imply that *nu/nu* mice contain lymphoid cells which can be activated *in vivo* by an allogeneic stimulus and interleukin 2 to generate cytotoxic T cells.

Recent work has shown that interleukin 2 is released from Lyt 1 T cells in response to allogeneic and mitogenic stimuli¹⁸. *In vitro*, interleukin 2 replaces the Lyt 1 T-helper cell requirement of thymic Lyt 123 CTL precursors, thus allowing the latter to differentiate in response to antigenic stimuli into alloreactive of H-2-restricted Lyt 23 CTLs (ref. 23 and C.H. *et al.*, in preparation). Systemic *in vivo* application of interleukin 2 plus alloantigen is shown here to trigger in otherwise T-cell immunoincompetent *nu/nu* mice the induction of alloreactive CTLs. Therefore, *nu/nu* mice must possess interleukin 2-sensitive T-precursor cells endowed with the receptor repertoire required for alloreactivity.

One could argue that the thymic rudiment of *nu/nu* mice induces T-cell lymphopoiesis with a functional activity below normal detection. This low activity might be boosted by the *in vivo* activity of interleukin 2 to the levels described here. If so, *in vivo* application of interleukin 2 might be useful as an immunopharmacological agent for amplifying weak T-cell reactivity *in vivo*. If, however, the thymus defect in *nu/nu* mice is absolute, the results imply that interleukin 2 bypasses the requirement of a thymus during the *in vivo* differentiation of pre-thymocytes into

alloreactive CTLs. According to this reasoning, pre-thymic cells already contain the receptor repertoire required for alloreactivity. We do not know whether the repertoire for alloreactivity is dependent on pre-thymic somatic events or whether it is inherited from the germ line, as suggested by Jerne². Because the repertoire for alloreactivity might already be expressed on pre-thymic cells, and because alloreactive and H-2-restricted CTLs may be identical^{35,36}, it is also possible that the repertoire for extrinsic foreign antigens is expressed in pre-thymic precursor T cells. If so, we envisage, at the level of precursor T cells, distinct clones with the potential to react to an extrinsic antigen in the context of both syngeneic and allogeneic H-2 structures.

We thank Sabine Barth, Monika Schmidt and Rosi Trabschitt for technical help. This work was supported by the SFB 107, and the Stiftung Volkswagenwerk.

Note added in proof: Using the very same protocol we recently succeeded in inducing in *nu/nu* mice T helper cells specific for heterologous sheep erythrocytes (Stötter, Rude and Wayne, submitted for publication).

Chemical characterisation of the Fab and Fc fragments from surface immunoglobulin

Immunoglobulin (Ig) molecules of the M and D classes are present on the membranes of B lymphocytes (sIg), where they serve as antigen receptors^{1–6}. sIg is a biosynthetically stable membrane protein which requires either denaturing conditions or detergents to free it from other membrane constituents^{1,7–9}. Whether the right association of sIg with the membrane is due to the chemical nature of the sIg molecule itself or to another constituent of the membrane, and the mechanism by which the recognition of antigen becomes a signal for cell division and differentiation, have become topics of current interest. Several mechanisms by which the membrane-sIg association could be maintained have been proposed^{10–13}: the sIg could have a unique peptide structure and/or amino acid sequence responsible for stabilising the association; the carbohydrate composition of sIg could impart physical and/or chemical characteristics which maintain the association; sIg could be closely associated with another protein, the proreceptor, which would be responsible for holding the sIg in the membrane. Here, we use charge-shift electrophoresis¹⁴ to examine the detergent-binding properties of mouse sIgM and sIgD and the tryptic Fab and Fc fragments derived from these molecules. In this technique, hydrophobic proteins which bind detergent are recognised by an altered electrophoretic behaviour in the presence of charged detergents. Proteins which fail to bind detergent do not show a 'shift' in electrophoretic migration. Our results confirm the observation that sIg is a hydrophobic protein which binds detergent^{15–17}, and demonstrate that the site of detergent binding is located in the C-terminal portion of the sIg heavy chain.

Suspensions of murine splenocytes were radioiodinated and the labelled surface proteins solubilised by detergent lysis^{18,19}. sIgM, sIgD and the Fab and Fc fragments were isolated by a combination of affinity chromatography and tryptic digestion (Fig. 1). The ¹²⁵I-labelled lysate was divided into two aliquots. One aliquot was passed over an anti- μ affinity column; complete sIgM molecules were subsequently eluted from this column. The unbound material contained ¹²⁵I-sIgD in addition to other labelled surface proteins. This eluate was digested with trypsin in conditions previously shown to give complete cleavage of sIgD into Fab and Fc fragments²⁰. The digest was applied to an anti- δ affinity column from which sIgD Fc fragments were eluted. The digest, depleted of Fc fragments, was passed over an anti-light-chain column from which the sIgD Fab fragments were subsequently obtained.

The second aliquot was subjected to a similar procedure except that the anti- δ affinity column preceded, and the anti- μ affinity column followed, the proteolytic digestion. The hydrophobicity of the sIg molecules and tryptic fragments was examined by charge-shift electrophoresis¹⁴ (Fig. 2) and gave the following results. Neither the myeloma proteins, run as standards, nor the sIg or sIg fragments moved from the origin in the presence of the non-ionic detergent Triton X-100. In the presence of the anionic detergent deoxycholate, anodal migra-

tion of the sIgM, sIgD, sIgM Fc and sIgD Fc fragments was observed.

These results demonstrated that the Fc fragments of sIg contain the hydrophobic regions responsible for detergent binding. Perhaps the simplest explanation for these observations is that sIgM and sIgD have a unique stretch of hydrophobic amino acids at, or near to, the C-terminus of the heavy chain. The recent experiments of Williams *et al.*²¹ support this hypothesis, although the earlier experiments of Walsh and Crumpton²² and McIlhinney *et al.*²³ lead to a contrasting, although unproven conclusion.

Another possibility is that the hydrophobicity was due to incomplete glycosylation of the sIg. Several arguments against a relationship between the extent of glycosylation and detergent binding can be made. First, removal of carbohydrate residues from secreted human IgM myeloma proteins with neuraminidase and β -galactosidase did not result in an appearance of detergent-binding properties (J.L., unpublished observation). Second, secreted IgG does not contain a sub-fraction which binds detergent¹⁴, although the carbohydrate composition of these molecules is known to be heterogeneous²⁴. Third, other integral membrane proteins, such as the murine and human histocompatibility antigens, are highly glycosylated, hydrophobic and capable of binding detergent. Finally, intracellular 7S IgM from mouse myeloma cells, although deficient in carbohydrate²⁵, does not bind detergent in the charge-shift electrophoresis assay (R.M.E.P., unpublished work).

It is possible that the hydrophobicity of sIg was actually due to a closely associated, noncovalently bound hydrophobic proreceptor undetected by the iodination procedures. This possibility is less likely in view of the observations that biosynthetically radiolabelled intracellular Ig from the murine B-cell leukaemia 70Z/3 (J.L. and C. J. Paige, manuscript in preparation) or from chicken bursal cells²⁶ showed the same electrophoretic behaviour as we report for murine sIgM and sIgD. This biosynthetically labelled Ig was free of peptides other than heavy and light chains when the cells were solubilised with both NP-40 and 2% sodium deoxycholate^{13,27}.

Although not conclusive, our results are consistent with the interpretation that the hydrophobic nature of sIg is sufficient to account for the stability of the plasma membrane-sIg asso-

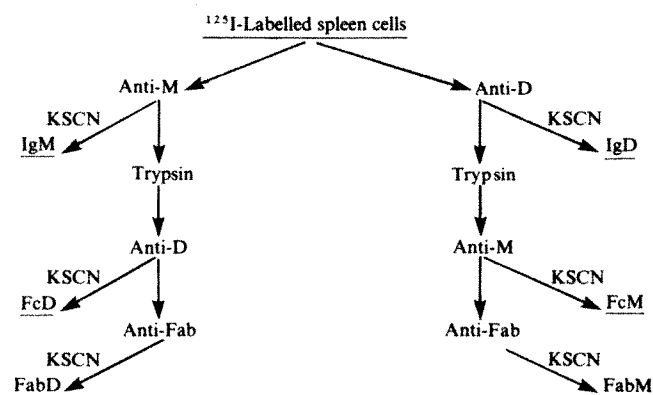

Fig. 1 Preparation of complete and tryptic cleaved sIg. The lysate was divided into two aliquots and subjected to the first stage of affinity chromatography as described in the text. The sIgD-containing lysate was digested with TPCK-trypsin (Sigma) at 0.1 mg ml⁻¹ for 30 min at room temperature. The sIgM-containing lysate was treated identically except that incubation was at 37 °C for 3 h. The digestion was stopped by the addition of 1 mg ml⁻¹ soybean trypsin inhibitor, 1 mg ml⁻¹ egg white trypsin inhibitor and 1 mM phenylmethylsulphonyl fluoride. The second and third stages of affinity chromatography followed. Material bound to the affinity resins was eluted with 4 M KSCN containing 0.5% Triton X-100 after washing the column with 0.5% Nonidet P-40 phosphate-buffered iodine, pH 7.4, and four column volumes of 1 M KSCN containing 0.5% Triton X-100. The samples were dialysed against 0.05 M glycine-NaOH, 0.1 M, NaCl and 0.5% Triton X-100, pH 9.0.

Fig. 2 Charge-shift electrophoresis of sIg and tryptic fragments. Rabbit antisera to mouse μ -chains, δ -chains and κ -chains²⁸ were precipitated at 1.6 M ammonium sulphate and the immunoglobulin fractions coupled to CH-Sepharose 4B (Pharmacia) using carbodiimide according to the manufacturer's instructions. The anti- μ and anti- δ sera were without specificity towards the Fab portions of the molecules. Spleen cells from male CBA mice were radioiodinated by the lactoperoxidase-catalysed procedure and lysed in 0.5% (w/v) Nonidet P-40^{18,19}. The nuclei and cellular debris were removed by centrifugation at 15,000g for 15 min, 0 °C, and the free ¹²⁵I removed by chromatography on Sephadex G-25. sIgM, sIgD and their respective Fc fragments were prepared as described in Fig. 1 legend. Charge-shift electrophoresis in 1% agarose (w/v) gels containing either 0.5% Triton X-100 or 0.5% Triton X-100 plus 0.25% (w/v) sodium deoxycholate was carried out as described by Helenius and Simons¹⁴. Sodium deoxycholate, 2%, was added to the samples at least 5 h before electrophoresis. Gels were fixed in methanol/acetic acid/water, 1:1:8, and dried onto chromatography paper. Autoradiography using pre-flashed film and fast tungstate intensifying screens was carried out according to the method of Laskey and Mills²⁹. In the bottom panel, the anodal migration of sIgM, sIgD and their respective Fc fragments is evident. The ¹²⁵I-labelled serum IgM and IgG samples were purified mouse myeloma proteins MOPC 104E and Adj PCS, respectively. The migration of these samples with or without sodium deoxycholate was unaffected by prior chemical reduction with dithiothreitol or treatment with 4 M KCNS and dialysis against the electrophoresis buffer.

ciation. The contribution of the Fc-localised hydrophobic region of sIg to the mechanism of signal transduction, whether the sIg is a transmembrane protein, and the structural differences between sIg and serum immunoglobulin of the same class, remain to be determined.

Inherited defect in a Na⁺, K⁺-co-transport system in erythrocytes from essential hypertensive patients

Ricardo P. Garay, Georges Dagher, Marie-Gabrielle Pernollet, Marie-Aude Devynck & Philippe Meyer

U7 INSERM/ERA 336 CNRS, Hôpital Necker, 161 rue de Sèvres, 75015 Paris, France

The Na⁺ and K⁺ electrochemical gradients across cell membranes are believed to be maintained by the action of a Na⁺, K⁺-pump¹⁻³. In human erythrocytes this pump exchanges internal Na⁺ for external K⁺ in approximately a 1.5 ratio^{4,5}. Thus, when Na⁺-loaded/K⁺-depleted erythrocytes are incubated in physiological conditions they tend to recover their original low Na⁺/high K⁺ content. Surprisingly, in erythrocytes from healthy donors the net Na⁺ extrusion/K⁺ influx ratio exceeds the 1.5 ratio predicted for Na⁺, K⁺-pump-mediated fluxes whereas it is similar to this value in erythrocytes from essential hypertensive patients and some of their descendants⁶. We now report that this difference is due to the presence of a Na⁺, K⁺-co-transport system in normal erythrocytes which extrudes both internal Na⁺ and K⁺ and is functionally deficient in erythrocytes of essential hypertensive patients and some of their descendants. No difference in passive Na⁺ permeability could be detected between normotensive and hypertensive subjects.

The different transmembrane pathways involved in net Na⁺ and K⁺ transport in Na⁺-loaded/K⁺-depleted erythrocytes were analysed in the following groups⁶: normotensive and secondary hypertensive subjects devoid of familial hypertension, benign and accelerated essential hypertensive patients and those offspring of hypertensive patients with an abnormal low ratio of Na⁺/K⁺ net fluxes (⊕ normotensives).

The presence of ouabain (0.1 mM) in the incubation medium greatly reduced net Na⁺/K⁺ movements in all subjects studied (Table 1). If we assume that the ouabain-sensitive fraction of the total fluxes corresponds to the exchange of internal Na⁺ for external K⁺ catalysed by the Na⁺, K⁺-pump (see ref. 7 for discussion), three conclusions can be drawn:

First, in erythrocytes of ⊕ normotensives and benign essential hypertensive patients the pump fluxes are 20-40% higher than in normal erythrocytes. A high (Na⁺ + K⁺)ATPase activity has been recently reported for benign essential hypertensives⁸. This increased pump activity could result either from a more rapid rate of cation translocation or from a higher density of pump unities. To test this latter hypothesis we have studied the binding of ³H-ouabain which is known to label the (Na⁺ + K⁺)ATPase specifically. Scatchard analysis of ³H-ouabain binding to erythrocyte membranes indicated the presence of only one class of binding sites, the number of which did not significantly differ between the five groups (Table 1). In contrast, the apparent dissociation constant (K_D) varied from 3.7 × 10⁻⁹ M to 1.3 × 10⁻⁸ M. A correlation was found between the apparent dissociation constant and the pump activation (Fig. 1). It is interesting that a regulatory membrane protein changing the apparent affinity for the ouabain inhibition of the (Na⁺ + K⁺)ATPase has been described recently⁹. This phenomenon certainly merits further investigation.

Second, in all subjects the stoichiometry of the Na⁺, K⁺-pump is very close to that reported previously^{4,5}, that is, ouabain-sensitive Na⁺ efflux/K⁺ influx = -1.5; the minus sign indicates that the vectorial transports of Na⁺ and K⁺ have different signs.

Third, in the presence of 0.1 mM ouabain a net Na⁺ extrusion in an uphill direction against the electrochemical Na⁺ gradient was observed in erythrocytes of normotensive controls (and

The effect of ouabain on the net Na⁺ and K⁺ fluxes was studied by the method previously described⁶ with the following modifications: (1) the PCMBs concentration of the Na⁺-loading solution was reduced to 0.02 mM, (2) 2 mM adenine, 3 mM inosine and 2.9 mM Na⁺ phosphate buffer (pH 7.2 at 37° C) were added to the recovering solution. After recovery, the internal cation content was (mmol per l cells) 55–75 Na⁺ and 30–50 K⁺ and the increase in cell volume was less than 2%, (3) ouabain-sensitive fluxes were calculated by the difference between net Na⁺ and K⁺ fluxes in a Na⁺, K⁺-Ringer solution with and without ouabain 0.1 mM. At hours 0, 1, 2 and 3, two tubes were transferred to 0° C and the cells were washed three times with 150 mM choline Cl, 2.5 mM Tris-phosphate (pH 7.2 at 4° C) and 0.02 mM ouabain at 4° C. Na⁺, K⁺ and haemoglobin were measured in the same sample. To study the effect of furosemide on the ouabain-resistant net Na⁺ and K⁺ fluxes some additional modifications were introduced: (1) the Na⁺-loading solution was (mM) 250 choline Cl, 40 NaCl, 10 KCl, 2.5 Na phosphate (pH 7.2 at 4° C), 1 MgCl₂ and 0.02 PCMBs, (2) the recovering solution was K⁺ free. After recovery the reduction in cell volume was less than 3% and the internal cation content was 20–30 mmol per l cells of both Na⁺ and K⁺. Furosemide-sensitive fluxes were calculated by the difference between net Na⁺ and K⁺ fluxes in a medium containing (mM) 90 choline Cl, 60 NaCl, 2.5 Na phosphate (pH 7.2 at 37° C), 1 MgCl₂, 10 glucose and 0.1 ouabain with and without 1 mM furosemide. At each incubation time three tubes were removed from the incubation bath. Ouabain + furosemide-resistant net Na⁺ fluxes were measured in fresh cells. After removing the plasma and buffy coat, the cells were washed twice with 150 mM choline Cl. They were then incubated at 37° C in three different Na⁺-media containing (mM) 1 MgCl₂, 2.5 Tris-phosphate (pH 7.2 at 37° C), 10 glucose, 0.1 ouabain, 1 furosemide and 0, 75 or 150 NaCl (the isotonicity was maintained with choline Cl). At hours 0, 1 and 2, two tubes were transferred to 0° C and the cells were processed as before. The rate constant of Na⁺ permeability was obtained from the slope relating the ouabain- and furosemide-resistant net Na⁺ fluxes against the external Na⁺ concentration. Ouabain- and furosemide-resistant net K⁺ fluxes were measured in the same PCMBs-treated cells used for measuring furosemide-sensitive fluxes. Ouabain-binding experiments were carried out with washed erythrocytes incubated in (mM) 1 HEPES (pH 7.4), 150 NaCl, 3 ATP and 3 MgCl₂ for 3 h at 37° C with 5 × 10⁻¹⁰ M to 10⁻⁷ M ³H-ouabain (13 Ci mmol⁻¹, NEN). Results were corrected by subtracting the nonspecific binding measured in the additional presence of 10⁻⁶ M unlabelled ouabain. The values given represent mean ± s.d. and *n* denotes the number of subjects in each group. The statistical significance of the data was studied using the non-parametric test of Mann-Whitney.

* Net flux is given in mmol per l cells per h. A minus sign indicates a net cation extrusion, a plus sign a net cation influx. Na⁺/K⁺ values indicate the stoichiometry of Na⁺/K⁺ net fluxes, and Oub N_s the number of ouabain binding sites per cell.

† Rate constant of cation permeability in d⁻¹.

‡ P < 0.01; § < 0.001.

Fig. 1 Relationship between the Na⁺, K⁺-pump activation and the apparent dissociation constant of ouabain binding. ○, normotensive controls; ●, essential hypertensives; △, secondary hypertensives; ■, normotensives born of hypertensive parents.

secondary hypertensives). This confirms previous observations suggesting that the ouabain-resistant fluxes do not simply represent passive permeabilities¹⁰ and that the Na⁺, K⁺-pump is not the only mechanism ensuring a net cell Na⁺ extrusion^{11,12}. It is interesting that no ouabain-resistant net Na⁺ extrusion was observed in erythrocytes from ⊕ normotensives and essential hypertensive patients (Table 1).

In preliminary experiments we found that the pump-independent net Na⁺ extrusion of normal erythrocytes could be inhibited by raising the external K⁺ concentration, by adding 1 mM furosemide or by ATP depletion, thus showing properties similar to the Na⁺, K⁺-co-transport system described in rat¹³, avian¹⁴ and human erythrocytes^{15,16}. In certain experimental conditions, this system may extrude internal Na⁺ in an uphill direction against the electrochemical Na⁺ gradient, using the energy supplied by the downhill K⁺ extrusion across the electrochemical K⁺ gradient. This system was therefore investigated in experiments in which conditions were modified to measure satisfactorily the small ouabain-resistant net Na⁺ and K⁺ fluxes (see Table 1).

In the presence of 0.1 mM ouabain, the addition of 1 mM furosemide to normal erythrocytes loaded with Na⁺ and choline effectively inhibited a net Na⁺ and K⁺ extrusion coupled in a ratio slightly less than +1 (the plus sign indicates that vectorial transport of both ions has the same sign) (Table 1). In contrast,

Fig. 2 Histograms of the ratio of total Na^+/K^+ net fluxes represented as the percentage deviation from the Na^+/K^+ -pump stoichiometry. Continuous line represents normotensive controls (30 subjects) and dotted line essential hypertensive patients (54 subjects).

the net Na^+ and K^+ extrusion catalysed by this Na^+/K^+ -co-transport system is markedly reduced in erythrocytes of essential hypertensive patients and \oplus normotensives (Table 1). Although the Na^+/K^+ -co-transport fluxes are smaller than the pump fluxes, the fact that they have a positive stoichiometry as opposed to the negative stoichiometry of the Na^+/K^+ -pump (and of the passive net Na^+ and K^+ fluxes) introduces a marked difference between the stoichiometry of total net fluxes of essential hypertensives and normotensive controls (see Fig. 2).

Net Na^+ and K^+ fluxes in the presence of both ouabain (0.1 mM) and furosemide (1 mM) have the kinetic properties of passive 'leak' fluxes. In fresh red blood cells, the ouabain- and furosemide-resistant net Na^+ influx (1) increases linearly with the external Na^+ concentration, (2) is not modified by external K^+ and (3) becomes zero when the external Na^+ equals the internal Na^+ concentration (in mmol l^{-1} cell). Moreover, these properties do not seem to be modified by incubation with cold 0.02 mM 2,5-*p*-chloromercuribenzenesulphonate (PCMBs). As indicated in Table 1, no difference in the passive Na^+ permeability could be detected between erythrocytes of hypertensive patients and those of normotensive controls. The same is true for the passive K^+ permeability which was only measured in PCMBs-treated cells. Thus, the increase in the ouabain-resistant unidirectional Na^+ influx¹⁷ and Na^+ efflux¹⁸ previously reported in erythrocytes from essential hypertensives, rather than being due to an increased passive Na^+ permeability, might reflect a disorder in a specific transport system such as the ouabain-resistant one-to-one Na^+/K^+ exchange which is activated in erythrocytes from essential hypertensive patients¹⁹. If this were the case, the increased unidirectional Na^+ fluxes would not be related to our observations because the Na^+/K^+ exchange mechanism does not result in net Na^+ fluxes.

The results presented here indicate that the net extrusion of an erythrocyte Na^+ load is accomplished by two different mechanisms, the Na^+/K^+ -pump and Na^+/K^+ -co-transport, which operate against the passive net Na^+ fluxes. Furthermore, they suggest that an inherited defect in the Na^+/K^+ -co-transport system may be genetically associated with essential hypertension. In avian red cells this transport system participates in the regulation of cell volume and is under hormonal control. These observations have led us to formulate the hypothesis that essential hypertension may result from an inefficient hormonal regulation of the extrusion of a cell Na^+ load after an excess Na^+ intake due to a functional disorder of the Na^+/K^+ -co-transport system. Such a process in excitable cells of high surface/volume ratio, such as smooth muscle cells or catecholaminergic neurones, may lead to a temporary or permanent increase in intracellular Na^+ , producing critical changes capable of raising blood pressure^{20,21}. The high Na^+/K^+ -pump activity seen in \oplus normotensives and benign essential hypertensives may therefore represent a compensatory mechanism for extruding a cell Na^+ load and thus preventing severe hypertension in subjects with this genetic abnormality.

Mechanism of action of dietary fibre in the human colon

Alison M. Stephen & John H. Cummings

Dunn Clinical Nutrition Centre, Addenbrookes Hospital, Trumpington Street, Cambridge CB2 1QE, UK

Fibre, more than any other dietary component, affects human large bowel function, causing an increase in stool output, dilution of colonic contents, a faster rate of passage through the gut and changes in the colonic metabolism of minerals, nitrogen and bile acids^{1–6}. (Fibre here refers to 'dietary fibre', which comprises plant cell wall polysaccharides and lignin, and not to 'crude fibre'.) It is thought that these changes are brought about by fibre passing through the gut undigested and holding water within its cellular structure^{7,8}. Although the amount of water taken up *in vitro* varies for different types of fibre^{8–10}, this does not correlate in the expected way with the effects these materials have on colonic function⁹. This is because fibre is extensively degraded in the gut^{2,11}, probably by the colonic microflora^{12,13}. Using a newly developed method modified from ruminant nutrition for isolating bacteria, we have shown that the main component of human faeces is bacteria¹⁴. We show here that the way in which two contrasting types of dietary fibre act in the colon depends on the extent to which they are digested. Cabbage fibre, which is extensively broken down, provides a readily usable substrate for the stimulation of microbial growth, whereas wheat fibre remains largely undigested and retains water in the gut lumen.

Table 1 shows the effect of wheat fibre in six subjects. On the control diet, faecal solids were 55% bacteria, 17% undigested fibre and 24% water-soluble material. With fibre, stool output increased by 102 g per day (127%), of which 19 g was solids and 83 g water. Transit time decreased by 25.1 h and total nitrogen excretion increased from 1.5 to 2.0 g per day. The 19 g per day increase in excretion of solids was accounted for largely by an increase of 11.6 g per day in undigested fibre. Thus, only 36% of the wheat fibre added to the diet was digested in the gut.

If it is assumed that the extra fibre excreted was hydrated to the same extent as the total stool, which was 3.2 g water per g faecal solids, or 76.3% water, this would account for 48.7 g (48%) of the increase in faecal output. The water-holding

capacity of this wheat fibre, when measured *in vitro*, is in excess of 3.2 g water per g material⁹. Similarly, the extra bacteria excreted (2.3 g) would contribute 9.7 g (10%) of the increase at the same hydration. Bacteria are normally about 80% water¹⁵ and, as they comprise the major fraction of faecal solids, are an important water-holding component in the gut. The whole stool was wetter with the added fibre than on the control diet, which suggests that a further 20.5 g (20%) of the increase was water associated with the bacteria and fibre from the control diet. This leaves 23 g (22%) of the increase to be accounted for by water-soluble solids (5.1 g) and water (18.1 g), which may represent an increase in extracellular, or free, water in the stool.

Wheat fibre, therefore, by surviving digestion in the intestine, alters colonic function by holding water and thus increases the bulk of the colonic contents. Transit time is thereby decreased and less water is absorbed from the lumen. Scanning electron microscope studies of bran before and after passage through the gut suggest it retains its cellular structure virtually intact^{16,17}.

The changes seen with cabbage fibre were quite different. Stool output increased by 54.3 g per day (69%), a smaller increase than with wheat fibre but nevertheless highly significant. Transit time fell by 15.8 h and nitrogen excretion increased from 1.5 g to 2.1 g per day. The increase in stool output comprised 8.5 g per day solids and 45.8 g water. Of the solids only 1.6 g was undigested fibre, indicating that on average 92% of the cabbage fibre had been digested. The main increase was in bacterial solids (4.8 g) which, at the hydration of the stool (74.6%), accounts for 18.9 g (35%) of the increase in stool weight. The faeces were again better hydrated on the cabbage fibre diet than during the control, presumably because the increased bacterial mass stimulated faster transit and led to less water absorption from luminal contents by the large bowel mucosa. These changes in hydration account for a further 17.5 g (32%) of the stool output, the extra fibre excreted adds 6.3 g (12%), and the rest, 11.6 g (21%), is associated with the soluble component.

Cabbage fibre, therefore, influences colonic function through its stimulation of microbial growth. Analysis of the bacterial fraction for nitrogen (for three subjects) shows that 0.42 g of the 0.67 g per day (63%) increase in nitrogen excretion is associated with this fraction, whereas with wheat fibre (four subjects) only 0.18 g of the 0.53 g (34%) increase is in the bacteria¹⁸. The rest of the nitrogen is presumably present in the undigested cell-wall material.

Fibre provides a ready source of available carbohydrate to the microflora of the human colon, as it does in the rumen. On the

Table 2 Changes in faecal composition (g per day \pm s.e.m.) and transit time (h) with cabbage fibre

	Control diet	+Cabbage
Mean daily stool weight	88.2 \pm 9.8	142.5 \pm 16.1*
% Moisture	69.4 \pm 1.9	74.6 \pm 2.0†
Total solids	26.1 \pm 1.2	34.6 \pm 5.7*
Total nitrogen	1.5 \pm 0.1	2.1 \pm 0.1†
Transit time	79.5 \pm 10.4	63.7 \pm 8.0‡
Composition of solids (g per day)		
Neutral detergent fibre	4.1 \pm 0.2	5.7 \pm 0.4*
Water soluble	6.0 \pm 0.5	8.7 \pm 0.7†
Bacteria	14.5 \pm 1.1	19.3 \pm 0.8†

Six healthy male subjects, three of whom also took the bran, undertook the same protocol as outlined in Table 1. Instead of wheat fibre, 18.3 g per day of cabbage fibre was added to the diet.

* $P < 0.001$; † $P < 0.01$; ‡ $P < 0.05$.

basis of calculations from rumen physiology, the digestion of 16.4 g per day of fibre from cabbage would be expected to produce 0.44 g per day bacterial nitrogen, which approximates closely to the findings in this study (0.42 g per day).

Two distinct mechanisms thus emerge whereby fibre affects the human colon. We believe that the stimulation of microbial growth is the more usual one in man because very little fibre survives digestion by the bacteria when sources such as apple, carrot, guar (unpublished observations), pectin¹¹ or mixed diets^{2,21} are fed. Wheat fibre, and possibly cereals in general, may prove to be the exception as they have small cells with highly lignified cell walls which resist digestion.

The increase in excretion of bile acids, neutral sterols, nitrogen, fat, minerals and electrolytes which have been noted in other studies when fibre is fed, have been ascribed to the physical effect of the fibre itself^{2,3,19-23}. Because little fibre is excreted in the faeces, other explanations for these changes must be sought, perhaps taking account of the increase in bacterial mass.

On the control diet, both stool output and transit through the gut were significantly correlated in this study with faecal bacterial mass ($r = 0.84$ and -0.80 respectively). If, as has been suggested²⁴, colonic disease is more common in people who have small stool outputs and slow transit, the control of colonic microflora will be important in determining disease susceptibility in individuals. The type, amount and digestibility of fibre in the diet will, in turn, make a significant contribution to this.

Table 1 Changes in faecal composition (g per day \pm s.e.m.) and gut transit time (h) with wheat fibre

	Control diet	+ Wheat fibre
Mean daily stool weight	95.5 \pm 8.7	197.0 \pm 13.4*
% Moisture	71.1 \pm 1.5	76.3 \pm 1.2†
Total solids	27.0 \pm 1.2	46.0 \pm 1.1*
Total nitrogen	1.5 \pm 0.1	2.0 \pm 0.1†
Transit time	67.8 \pm 10.1	42.7 \pm 2.7‡
Composition of solids (g per day)		
Neutral detergent fibre	4.6 \pm 0.4	16.2 \pm 0.3†
Water soluble	6.5 \pm 0.5	9.2 \pm 0.4*
Bacteria	15.0 \pm 0.7	17.3 \pm 1.0‡

Six healthy male subjects, aged 22-38 yr, were given a controlled diet for 3 weeks consisting of everyday foods of overall daily composition: 385 g carbohydrate, 85 g protein, 108 g fat and 22 g dietary fibre. For a further 3-week period 18 g dietary fibre as bran was added to the diet. Further details of the study protocol and methods of preparation of the fibre are recorded elsewhere¹. Transit was measured by the continuous marker method²⁵. Faeces were collected throughout, and for each subject those from the last 7 days of each dietary period were pooled and freeze-dried. Daily excretion of fibre, as neutral detergent fibre²⁶, nitrogen by the Kjeldahl technique, bacterial mass and the water-soluble component of faeces were measured¹⁴.

BOOK REVIEWS

Phylogenetic hypotheses

R. D. Martin

THIRTEEN years have elapsed since the late Willi Hennig's influential textbook *Phylogenetic Systematics*, translated from the German manuscript by Dwight Davis and Zangerl, was originally published in 1966. Republication, with the addition of a brief but useful introduction by three disciples, comes at a time when Hennig's major contribution to the science of phylogenetic reconstruction has more-or-less achieved the widespread recognition that it deserves. This is also a particularly suitable time to take stock of Hennig's approach. Although *Phylogenetic Systematics* is set out with admirable clarity, considerable controversy has accompanied the dissemination and practical application of Hennig's concepts. The issues at stake can only be clearly appreciated by taking a step omitted by Hennig and many others in the field — namely, that of considering separately phylogenetic reconstruction and classification. For the first, Hennig has unquestionably introduced greater scientific precision, while for the second he has arguably generated further confusion.

The attempt to reconstruct phylogenetic history is, or should be, a scientific undertaking involving the identification of past evolutionary relationships ultimately embodied in the process of speciation. One of Hennig's most important innovations here lies in his explicit statement that mere assessment of degrees of morphological (or

Phylogenetic Systematics. By W. Hennig. Pp. 263. (University of Illinois Press: London, 1979.) £12.

other) similarity does *not* provide an adequate basis for accurate phylogenetic reconstruction. Any given group of organisms can be theoretically traced to an original stem species with a certain array of initial (plesiomorphous) characters, and retention of any of these characters as shared similarities among descendant species provides no information about subsequent branching in the evolutionary tree. Only derived (apomorphous) characters developed at some later stage and retained in certain descendants can be used as indicators of phylogenetic relationships within the group. Hennig provides a number of empirical guidelines for the differential assessment of shared similarities (plesiomorphous; apomorphous; convergent) in phylogenetic reconstruction, and concepts such as those of the character transformation series and of the sister group are of considerable heuristic value. However, as Hennig himself recognises, everything in the end boils down to a scientific estimation of probabilities. Thus, the accuracy of phylogenetic reconstruction depends on the validity of the theoretical principles used (hence the value of Hennig's contribution) and upon the diversity of the

characters examined.

Unfortunately, Hennig simultaneously maintains that classifications should be directly based upon the evolutionary branching pattern and the dates of divergence inferred. This controversial tenet has proved to have at least two great drawbacks. Firstly, there is no compelling reason to assume that classifications should only reflect inferences regarding the positions and timing of branching points in phylogenetic trees. Secondly, since every phylogenetic reconstruction represents a hypothesis based on estimation of probabilities, Hennig's prescription inevitably leads to a proliferation of alternative classifications and instability of higher taxonomic categories. Since classifications provide, among other things, the terms we use to discuss living organisms, taxonomic instability is associated with linguistic instability. This being the case, any recommendation to read Hennig's excellent logical dissection of the process of phylogenetic reconstruction must be tempered with the warning that classification (which inevitably involves numerous arbitrary decisions) will not necessarily benefit from too close an association with the phylogenetic hypotheses of individuals.

R.D. Martin is Reader in Physical Anthropology at University College, and Visiting Professor of Zoology at Birkbeck College, London, UK.

For the petroleum geologist

R.C. Selley

Petroleum Geochemistry and Geology. By J.M. Hunt. Pp.617. (Freeman: San Francisco and London, 1979.) £16.95.

THE application of chemistry to the study of oil generation, migration and maturation has a long history. It is only within the last decade, however, that geochemical exploration techniques have become an accepted tool in the oil industry. Dr Hunt has played a seminal role in these advances both in industry, with Exxon,

and latterly at Woods Hole. This book thus merits the attention of every petroleum geologist. It consists of twelve chapters, arranged in four parts: Introduction, Origin and Migration, Habitat, and Applications.

The Introduction begins with a short historical review and continues with an account of the early formation of life on Earth, photosynthesis, the carbon cycle and the preservation of organic carbon in sedimentary rocks. This is followed by a chapter on the chemistry of hydrocarbons, both those which occur naturally and those produced by refineries.

Part II, Origin and Migration, begins with a cursory review of the abiogenic theories of hydrocarbon formation before launching into an account of the chemistry of plant and animal tissues and the

diagenetic changes which they undergo on burial. The temperature required for oil generation is discussed from both theoretical and observational points of view. Gas generation is treated in a separate chapter. The final chapter of this section deals with the last great mystery of oil, namely the magic of primary migration from the source rock to the carrier beds.

Part III, Habitat, opens with an account of source rocks, discussing the oil and gas generating potential of the various types of kerogen, and reviewing the various palaeothermometers available from maturation studies. This is followed by a chapter on the variation and distribution of hydrocarbons in reservoirs, with respect to depth, age and degradation.

Part IV, Applications, shows how the data and concepts previously presented

may be used in hydrocarbon exploration. This begins with a review of surface manifestations of oil, both the visible seeps of oil and gas onshore and offshore, and surface geochemical prospecting. A chapter on subsurface prospecting follows, describing the analysis and interpretation of cuttings gas as well as ways in which source rocks may be studied to determine their oil or gas potential, and their degree of maturity.

The next chapter shows how crude oils may be correlated with their source beds, and the text concludes with a short account of geochemical prospect evaluation. Finally, there is a glossary, forty pages of references and author and subject indexes.

Inevitably, this book invites comparison with Tissot and Welte's recent book, *Petroleum Formation and Occurrence* (Springer: Berlin, Heidelberg and New York, 1978), on the same topic. They both cover the same subject matter and both draw freely (and with due acknowledgement) on each other's work. Both books are excellent and the only simple comparison that may be drawn is that Hunt's

book perhaps emphasises geology more than chemistry, while for Tissot and Welte's book the converse is true. Certainly, this reviewer, who is only a geologist, finds Hunt's book the easier to read.

The arrangement of the vast amount of material in a book of this kind presents many problems but could perhaps have been improved. For example, discussion of source rocks should perhaps precede an account of the emigration of hydrocarbons from them. Sections dealing with palaeo-temperature analysis could perhaps have been grouped together, and their relative merits and limitations contrasted, instead of their being distributed through several chapters of the book. Since oil and gas formation is so intimately related it seems an unnecessary distinction to discuss their genesis in separate chapters.

To counteract these comments, however, it must be stated that the book is well written, well researched and pleasantly produced. All the line illustrations have been specially prepared for this work and

each part begins with a half-tone plate. A particularly helpful feature is the inclusion of a summary and list of supplementary reading at the end of each chapter.

The wide range of case histories discussed is impressive. It is unusual to find a geologist of the USA who is familiar with, or at least prepared to quote, data from outside North America. This reviewer could spot only two important omissions. There was no reference to Porfir'ev's paper on the inorganic origin of oil (*Bull. Am. Ass. Petrol. Geol.* 58, 3-33, 1974). This is probably the most accessible exposition of the Russian igneous oil theory for readers in the free world. Several papers related to the correlation of vitrinite reflectivity and electron spin resonance are also omitted.

These are, however, minor blemishes on a major textbook. No petroleum geologist should be without a copy of *Petroleum Geochemistry and Geology*. □

R.C. Selley is Reader in Petroleum Geology at Imperial College, University of London, UK.

Plankton research

C.M. Yonge

Zoogeography and Diversity in Plankton. Edited by S. van der Spoel and A.C. Pierrot-Bults. Pp.410. (Edward Arnold: Maidenhead, 1979.) £37.50.

THIS most attractive book is a revelation of the extent and cohesion of plankton research. It appears at about the centenary of the initial work by Hensen which led, at the beginning of the century, to the formulation by the International Council for the Exploration of the Sea of a programme involving the quantitative study of plankton in relation to hydrography on the one hand and fisheries on the other. These first collections and counting of plankton have gradually spread over the face of globe, with whaling investigations in the Southern Ocean and the International Indian Ocean Expedition extending knowledge into these previously little known areas.

Problems of distribution and of speciation, the dominant themes in this book, are vast and perplexing. In contrast to the terrestrial habitat, that of marine plankton is three-dimensional and continuous. There are notable distinctions between neritic (coastal) and oceanic populations, with latitudinal divisions largely temperature based and different biotopes in depth represented by epipelagic, mesopelagic and bathypelagic plankton. Distinctions between habitats are often best defined by the resident 'indicator' species, most frequently

chaetognaths. The *Challenger* studies of Murray and Renard on the deposition of planktonic skeletons on the ocean floor are the basis of modern work on the history of ocean basins and provide important evidence concerning continental drift.

An adequately authoritative survey of this immense field demands specialist treatment and most exacting editorial standards. Both are supplied by the contributions of fourteen authors from seven countries, most competently

organised by S. van der Spoel and A.C. Pierrot-Bults of the Institute of Taxonomic Zoology, University of Amsterdam. Clearly drawn figures and an extensive literature list complete the attractions of a book which presents information essential to all interested in the full extent of biological enquiry. It makes immediate appeal to the scientific imagination. □

Sir Maurice Yonge is Honorary Fellow in Zoology at the University of Edinburgh, UK.

Light physics

P. W. Hawkes

Optoelectronic Devices and Optical Imaging Techniques. By D. A. Ross. Pp. 137. (Macmillan: London, 1979.) Hardback £12; paperback £4.95.

THIS clear, simple introduction to a range of devices that convert electrical energy into light or generate such energy from light will appeal to a wide student audience, particularly to those who need to acquire only a smattering of the physics involved before exploring the many applications. The text is orientated towards specific devices, chapters being devoted to LEDs, photoconductors, photodiodes and phototransistors, solar cells and laser diodes; two other chapters are concerned with noise in such devices and in optical recording media, first film and then CCDs. All these are described in easy, uncomplicated language and illustrated

with uncluttered line diagrams and a photograph showing CCD-aided decapitation of carrots! I was a little startled to encounter, for the first time for many years, the jovial, avuncular style of older school textbooks; a line diagram is described as "An artist's impression of a photon", we are told that "It would be a minor disaster to be forced to abandon Fourier analysis . . .", but isolated examples cannot properly convey the flavour which nonetheless pervades the book.

The publishers have sensibly also brought out the book in paperback. Libraries will of course be more interested in the cased edition, but the paperback version is good value at £4.95; it should sell well, not only to students but to others, since plenty of people are interested in understanding these devices by which they are surrounded. □

P.W. Hawkes is Maître de Recherches in the Laboratoire d'Optique Electronique du CNRS, Toulouse, France.

For the first time...

interdisciplinary coverage of inflammation in a major new series

HANDBOOK OF INFLAMMATION

edited by L.E. Glynn, John. C. Houck and Gerald Weissmann

This series has been created in response to a real demand for interdisciplinary coverage of the inflammatory process. Each volume, edited by acknowledged experts, will focus on a major aspect of inflammation, thereby structuring the voluminous literature available into a concise definition of the 'state of the art' of each particular topic.

The creation of this series marks a significant step forward in the development of a coherent dialogue across the disciplines - and biochemists and biologists alike should welcome these first two volumes.

CHEMICAL MESSENGERS OF THE INFLAMMATORY PROCESS

edited by J.C. HOUCK

1979 xviii+422 pages Price: US \$75.00/Dfl. 154.00 ISBN 0-444-80121-9

This volume is devoted to the chemical messengers of the inflammatory process. The book is divided into eleven sections, each of which discusses different aspects of the various chemical mediators with particular emphasis on the importance of the mediators to the overall process. Special attention is focused on the issue of the increased permeability of the microcirculation and the proliferation of various cellular elements after tissue catabolism has occurred.

CONTENTS: Introduction (*J.C. Houck*). Histamine - Mediator and Modulator in Inflammation (*W.W. Busse*). Kinins and the Kinin System as Inflammatory Mediators (*H.Z. Movat*). Prostaglandins (*S.H. Ferreira*). Complement and Chemotaxis (*P.A. Ward, T.E. Hugli and D.E. Chenoweth*). Hageman Factor and the Contact Activation System (*R.C. Wiggins and C.G. Cochrane*).

Lymphokines and Cytokines (*V. Ewan and T. Yoshida*). Lysosomal Factors in Inflammation (*J.M. Gleisner*). Acid Cathepsins (*J.F. Woessner, Jr.*). Macrophage Growth Factor (*Y. Naum*). Tumour Angiogenesis (*D.H. Ausprunk*). The Place of Chalone among the Regulators of Cell Production in Inflammation (*E.B. Laurence*).

In Preparation:

Volume 2

THE CELL BIOLOGY OF INFLAMMATION

edited by GERALD WEISSMANN

1980 752 pages Price: US \$112.25/Dfl. 230.00 ISBN 0-444-80141-3

CONTENTS: The cells of inflammation: a general view. (*D.F. Bainton*). The microvascular system. (*D. Shepro*). The response of the microcirculation to inflammation. (*J.R. Casley-Smith*). The cell biology of platelets. (*J.G. White and J.M. Gerrard*). The platelet as an inflammatory cell. (*R.L. Nachman and B.B. Weksler*). The neutrophil. (*M. Baggiolini*). Cellular properties of eosinophils: Regulatory, protective and potentially pathogenetic roles in inflammatory states. (*J.A. Smith and E.J. Goetzl*). Cell biology of mast cells and basophils. (*D. Lagunoff and E.Y. Chi*). Granulocyte adherence. (*R.R. MacGregor*). The Cell biology of leukocyte chemotaxis. (*J.I. Gallin*). The metabolic

response to phagocytosis. (*D. Roos*). Intra and extracellular secretion from polymorphonuclear leukocytes. (*S.T. Hoffstein*). The effects of lysosomal enzymes on extracellular substrates. (*H.D. Keiser*). Monocytes and macrophages - Aspects of their cell biology. (*P.J. Edelson*). The secretion of hydrolytic enzymes by mononuclear phagocytes. (*P. Davies and R.J. Bonney*). The cell biology of granulomas (Aggregates of inflammatory cells) with a note on giant cells. (*K.S. Warren*). Subpopulations of lymphocytes - The lymphocyte as a cell structure. (*R. Robineaux, A. Anteunis and S.M. Dumitrescu*). The cell biology of blastogenesis. (*B.S. Handwerker and S.D. Douglas*).

REVIEWS IN INORGANIC CHEMISTRY

Edited by

H.D.B. Jenkins

Department of Chemistry and Molecular Sciences
University of Warwick, Coventry, England

D.F.C. Morris

Nuclear Science Centre, Department of Applied Chemistry
Brunel University, Uxbridge, England

Aims and Scope

This journal was instituted for the rapid publication of succinct, authoritative articles describing recent advances in inorganic chemistry. These may be quite short reports where authors discuss their own work in the context of the work of others in the field. Longer surveys covering the broader literature are also acceptable. The reviews will include all aspects of inorganic chemistry, such as, solution chemistry, coordination chemistry, kinetics, organometallics thermodynamics, electrochemistry, geochemistry, crystallography, and theoretical, nuclear, industrial, biological, and medical inorganic chemistry. In this way it is hoped to provide interplay of ideas. Articles which develop new insights and which promote new research activity are particularly welcome. Our aim is to provide a breadth of coverage which will enable research chemists and students to keep abreast of the latest developments in pure and applied inorganic chemistry.

Journal of Labelled Compounds & Radiopharmaceuticals

Edited by

A.T. Balaban

Institute of Atomic Physics,
Bucharest, Rumania

E.A. Evans

The Radiochemical Centre,
Amersham, England

P. Osinski

Université Catholique de Louvain, Unité de
Médecine Expérimentale, Brussels, Belgium

G. Stöcklin

Institut für Chemie der Kernforschungsanlage
Jülich GmbH, Germany

T.W. Whaley

Los Alamos Scientific Laboratory,
University of California, U.S.A.

A.P. Wolf

Department of Chemistry,
Brookhaven National Laboratory, New York, USA

Aims and Scope

The major purpose of this journal is to publish material on the synthesis of labelled compounds involving stable and radioactive nuclides. This includes all compounds in which the natural composition of one or more of its constituent atoms has been altered. Manuscripts dealing with new syntheses, special purification methods, analytical problems, quality control, autoradiolysis, production and handling of nuclides (for use as radiopharmaceuticals), problems involving the use of nuclides near natural abundance to highly enriched nuclides, special problems involving multi-curie amounts of activity and other pertinent problems will be considered for publication. Manuscripts dealing with radiopharmaceuticals where the focus is on preparation of the necessary nuclides and compounds or on the many special problems relating to synthetic and production work in this area will receive special attention.

Announcement and Call For Papers

Journal of CLIMATOLOGY

Edited by

Professor S. Gregory

Department of Geography, University of Sheffield

Aims and Scope

The literature of climatology is very widely dispersed through a variety of journals, the major focus of which may be meteorological, hydrological or geographical. There is therefore the need for an international journal which spans and reflects the specific field of climatology as a whole. The **Journal of Climatology** which will appear quarterly, will aim to satisfy this need through basic research papers, major review articles and current book reviews. The subject matter of the journal will comprise the breadth and complexity of climatology, with a catholic approach being adopted to content and theme. It is intended that descriptive enquiries should be counter-balanced by synoptic and dynamic climatology, global and regional studies complemented by local and micro-climatological investigations, mathematical modelling contrasted with work in applied climatology, and studies of present-day conditions illuminated by the complexity of past and future climatic changes. Thus it is expected that, apart from its basic and fundamental role in climatology itself, the journal should also have relevance for a wide range of related disciplines.

Journal of Climatology — QUARTERLY — STARTING 1981

A specimen copy and/or further information are available on request from either of the addresses below. If you have a contribution to make, please write to Dr. H.A. Jones at the Chichester address.

Announcement and Call For Papers

From January 1981 the well established Wiley journal 'EARTH SURFACE PROCESSES' will increase its scope and cover a more extensive subject area. From that date it will become:

Earth Surface Processes and Landforms

The Journal of the
British Geomorphological Research Group

Managing Editor:

Professor Michael J. Kirkby,

*Department of Geography, University of Leeds,
Leeds LS2 9JT*

Aims and Scope

'Earth Surface Processes and Landforms' will provide a journal for the publication of research papers on all aspects of geomorphology interpreted in its widest sense. The subject matter has now been broadened to include the following topics in pure and applied geomorphology:

PROCESSES: Hillslope, fluvial, coastal, aeolian, glacial, and periglacial processes of erosion and deposition; Process mechanics and modelling; Surface water and sediment movement; Hydrology and watershed management; Natural hazards and extreme events; Landslides; **LANDFORMS:** Landform evolution and analysis; Terrain analysis and morphometry; Landform genesis and chronology; Landform modelling; **SOILS AND WEATHERING:** The physical and chemical breakdown of the Earth's surface — regoliths and soils; Surface geochemistry; Solute and nutrient cycling; Soil dynamics and erosion; Soil properties and mechanics; Soil development and toposequences; **ENVIRONMENTS:** Landforms and processes of polar, temperate, arid and tropical regions; **APPLIED GEOMORPHOLOGY:** The application of relevant methods to the solution of planning, environmental, management or engineering problems.

The Journal is sponsored and supported by the British Geomorphological Research Group through editors appointed by the Group.

A new book from Butterworths

Kinetics and Dynamics of Elementary Gas Reactions

Butterworths Monographs in Chemistry and
Chemical Engineering Series

Ian W.M. Smith

This book examines the nature of elementary
chemical reactions as individual molecular processes.
A major goal of the work is to trace the connection
between the fundamental character of a chemical
system and its rate of reaction.

The first half of the text describes the theoretical
and conceptual background to the subject. The
remainder of the book reviews the results of
experiments on elementary reactions, pointing out
the advantages and limitations of different experi-
mental methods.

Transfer RNA

J.P. Goddard

Transfer RNA: Structure, Properties, and Recognition. Edited by P.R. Schimmel, D. Söll, and J.N. Abelson. Pp.577. (Cold Spring Harbor Laboratory: New York, 1979.) \$60.

NEARLY a quarter of a century has passed since the existence of the small adapter molecules known as transfer RNA was predicted. Their subsequent study has been motivated by their properties. They are relatively small and their central role in protein synthesis involves many specific interactions with proteins and nucleic acids. Furthermore they have since been strongly implicated in regulation of gene expression. The extent of this study is reflected in the fact that two volumes — the second is on biological aspects — were found necessary to fulfil the aim of summarising the knowledge of tRNA up to about the end of 1978.

The means to that end is, as in previous Cold Spring Harbor monographs, a series of articles by specialists in a particular aspect of tRNA who participated in the Transfer RNA Meeting at Cold Spring Harbor in August 1978. These articles have been supplemented by four appendices — on tRNA sequences and a proposed numbering scheme, on modified nucleosides and their chromatographic mobilities, and the characteristics of aminoacyl-tRNA synthetases. This first volume contains some thirty-one articles covering aspects of primary structure and isolation, crystal structure analysis, solution studies, aminoacyl-tRNA synthetases, synthetase recognition, and interaction with the ribosome.
